Abstract

Several well-studied graph problems aim to select a largest (or smallest) induced subgraph with a given property of the input graph. Examples include maximum independent set, maximum planar graph, maximum induced clique, minimum feedback vertex set, and many others. In online versions of these problems, the vertices of the graph are presented in an adversarial order, and with each vertex, the online algorithm must irreversibly decide whether to include it into the constructed subgraph, based only on the subgraph induced by the vertices presented so far. We study the properties that are common to all these problems by investigating the generalized problem: for an arbitrary but fixed hereditary property \( \pi \), find some maximal induced subgraph having \( \pi \). We investigate this problem from the point of view of advice complexity, i.e., we ask how some additional information about the yet unrevealed parts of the input can influence the solution quality. We evaluate the information in a quantitative way by considering the best possible advice of given size that describes the unknown input. Using a result from Boyar et al. [STACS 2015, LIPIcs 30], we give a tight trade-off relationship stating that for inputs of length \( n \) roughly \( n/c \) bits of advice are both needed and sufficient to obtain a solution with competitive ratio \( c \), regardless of the choice of \( \pi \), for any \( c \) (possibly a function of \( n \)). This complements the results from Bartal et al. [SIAM Journal on Computing 36(2), 2006] stating that, without any advice, even a randomized algorithm cannot achieve a competitive ratio better than \( \Omega(n^{1-\log 4/3-o(1)}) \). Surprisingly, for a given cohereditary property \( \pi \) and the objective to find a minimum subgraph having \( \pi \), the advice complexity varies significantly with the choice of \( \pi \). We also consider a preemptive online model, inspired by some application mainly in networking and scheduling, where the decision of the algorithm is not completely irreversible. In particular, the algorithm may discard some vertices previously assigned to the constructed set, but discarded vertices cannot be reinsered into the set. We show that, for the maximum induced subgraph problem, preemption does not significantly help by giving a lower bound of \( \Omega(n/(c^2 \log c)) \) on the bits of advice that are needed to obtain competitive ratio \( c \), where \( c \) is any increasing function bounded from above by \( \sqrt{n/\log n} \). We also give a linear lower bound for \( c \) close to 1.

1 Introduction

Online algorithms get their input gradually, and this way have to produce parts of the output without full knowledge of the instance at hand, which is a large disadvantage compared to classical offline computation, yet a realistic model of many real-world scenarios [5]. Most of the offline problems have their online counterpart. Instead of asking about the time and space complexity of algorithms to solve a computational problem, competitive analysis is commonly used as a tool to study how well online algorithms perform [5,18] without any time or space restrictions; the analogous offline measurement is the analysis of the approximation ratio. A large class of computational problems for both online and offline computation are formulated on graphs; we call such problems (online) graph problems.

In this paper, we deal with problems on unweighted undirected graphs that are given to an online algorithm vertex by vertex in consecutive discrete time steps. Formally, we are given a graph \( G = (V,E) \), where \(|V| = n\), with an ordering \( \prec \) on \( V \). Without loss of generality, assume \( V = \{v_1, \ldots, v_n\} \), and \( v_1 \prec v_2 \prec \ldots \prec v_n \) specifies the order in which the vertices of \( G \) are presented to an online algorithm; this way, the vertex \( v_i \) is given in the \( i \)th time step. Together with \( v_i \), all edges \( \{v_j,v_i\} \in E \) are revealed for all \( v_j \prec v_i \). If \( v_i \) is revealed, an online algorithm must decide whether to accept \( v_i \) or discard it. Neither \( G \) nor \( n \) are known to the online algorithm. We study two versions of online problems; with and without preemption. In the former case, the decision whether \( v_i \) is accepted or not is definite. In the latter case, in every time step, the online algorithm may preempt (discard) some of the vertices it previously accepted; however, a vertex that was once discarded cannot be part of the solution anymore.

For an instance \( I = (v_1, \ldots, v_n) \) of some graph problem, we denote by \( \text{Alg}(I) \) the solution computed by some online algorithm \( \text{Alg} \); \( \text{Opt}(I) \) denotes an optimal solution for \( I \), which can generally only be computed with the full knowledge of \( I \). We assume that \( I \) is constructed in an adversarial manner to give worst-case bounds on the solution quality of any online algorithm. This means that we explicitly think of \( I \) as being given by an adversary that knows \( \text{Alg} \) and wants to make it perform as poorly as possible; for more details, we refer to the standard literature [5].

For maximization problems with an associated profit function called profit, an online algorithm \( \text{Alg} \) is called \( c \)-competitive if, for every instance \( I \) of the given problem, it holds that

\[
\text{profit}(\text{Alg}(I)) \geq \frac{1}{c} \cdot \text{profit}(\text{Opt}(I)) ;
\]

likewise, for minimization problems with a cost function called cost, we require

\[
\text{cost}(\text{Alg}(I)) \leq c \cdot \text{cost}(\text{Opt}(I))
\]

for every instance \( I \). In this context, \( c > 1 \) may be a constant or a function that increases with the input length \( n \). We will use \( c \) and \( c(n) \) interchangeably to refer to the competitive ratio; the latter is simply used to emphasize that \( c \) may depend on \( n \).

Throughout this paper, \( \log \) denotes the binary logarithm \( \log_2 \). For \( q \in \mathbb{N} \), let \([q] = \{0, \ldots, q - 1\}\).

Instead of studying specific graph problems, in this paper, we investigate a large class of such problems, which are defined by hereditary properties. This class includes many well-known problems such as maximum independent set, maximum planar graph, maximum induced clique, and maximum acyclic subgraph. The cohereditary problems we consider are online versions of the offline problem of searching for a specific structure within a graph. An
example is to find the shortest cycle; this defines the girth of the graph. Online cycle finding was considered by Boyar et al. \[7\].

We call any collection of graphs a graph property \(\pi\). A graph has (or satisfies) property \(\pi\) if it is in the collection. Examples include the property of being planar (the collection contains all planar graphs), or being an independent set (the collection contains all graphs with no edges). We only consider properties that are non-trivial, i.e., they are both true for infinitely many graphs and false for infinitely many graphs. A property is called hereditary if it holds that, if a graph \(G\) satisfies \(\pi\), then also any induced subgraph \(G'\) of \(G\) satisfies \(\pi\); conversely, it is called cohereditary if it holds that, if a graph \(G\) satisfies \(\pi\), and \(G\) is an induced subgraph of \(G'\), then also \(G'\) satisfies \(\pi\). For a graph \(G = (V, E)\) and a subset of vertices \(S = \{v_1, \ldots, v_i\} \subseteq V\), let \(G[S]\) (or \(G[v_1, \ldots, v_i]\)) denote the subgraph of \(G\) induced by the vertices from \(S\). For a graph \(G = (V, E)\), let \(\overline{G} = (V, \overline{E})\) be the complement of \(G\), i.e., \(\{u, v\} \in \overline{E}\) if and only if \(\{u, v\} \not\in E\). Let \(K_n\) denote the complete graph on \(n\) vertices, and let \(\overline{K}_n\) denote the independent set on \(n\) vertices. We consider the online version of the problem of finding maximal (minimal, respectively) induced subgraphs satisfying a hereditary (cohereditary, respectively) property \(\pi\), denoted by \(\text{MAX-}\pi\) (\(\text{MIN-}\pi\), respectively). For the ease of presentation, we will call such problems hereditary (cohereditary, respectively) problems. Let \(S_{\text{ALG}} := \text{Alg}(I)\) denote the set of vertices accepted by some online algorithm \(\text{Alg}\) for some instance \(I\) of a hereditary problem. Then, for \(\text{MAX-}\pi\), the profit of \(\text{Alg}\) is \(|S_{\text{ALG}}| := \text{profit}(\text{Alg}(I))\) if \(G[S_{\text{ALG}}]\) has the property \(\pi\) and \(-\infty\) otherwise; the goal is to maximize the profit. Conversely, for \(\text{MIN-}\pi\), the cost of \(\text{Alg}\) is \(|S_{\text{ALG}}| := \text{cost}(\text{Alg}(I))\) if \(G[S_{\text{ALG}}]\) has the property \(\pi\) and \(-\infty\) otherwise; the goal is to minimize the cost. As an example, consider the online maximum independent set problem; the set of all independent sets is clearly a hereditary property (every independent set is a feasible solution, and every induced subset of an independent set is again an independent set). When a vertex is revealed, an online algorithm needs to decide whether it becomes part of the solution or not. The goal is to compute an independent set that is as large as possible; the profit of the solution is thus equal to \(|S_{\text{ALG}}|\). It is straightforward to define the problem without or with preemption.

In this paper, we study online algorithms with advice for hereditary and cohereditary problems. In this setup, an online algorithm is equipped with an additional resource that contains information about the instance it is dealing with. A related model was originally introduced by Dobrev et al. \[9\]. Revised versions were defined by Emek et al. \[11\], Böckenhauer et al. \[4\], and Hromkovič et al. \[12\]. Here, we use the model of the latter two papers. Consider an input \(I = (v_1, \ldots, v_n)\) of a hereditary problem. An online algorithm \(\text{Alg}\) with advice computes the output sequence \(\text{Alg}_\phi(I) = (y_1, \ldots, y_n)\) such that \(y_i\) is computed from \(\phi, v_1, \ldots, v_i\), where \(\phi\) is the content of the advice tape, i.e., an infinite binary sequence. We denote the cost (profit, respectively) of the computed output by \(\text{cost}(\text{Alg}_\phi(I))\) (\(\text{profit}(\text{Alg}_\phi(I))\), respectively). The algorithm \(\text{Alg}\) is \(c\)-competitive with advice complexity \(b(n)\) if, for every \(n\) and for each \(I\) of length at most \(n\), there exists some \(\phi\) such that \(\text{cost}(\text{Alg}_\phi(I)) \leq c \cdot \text{cost}({\text{OPT}}(I))\) (\(\text{profit}(\text{Alg}_\phi(I)) \geq (1/c) \cdot \text{profit}(\text{OPT}(I))\), respectively) and at most the first \(b(n)\) bits of \(\phi\) have been accessed by \(\text{Alg}\).\(^1\) We sometimes simply write \(b\) instead of \(b(n)\) to increase readability.

The motivation for online algorithms with advice is mostly of a theoretical nature, as we may think of the information necessary and sufficient to compute an optimal solution as the

\(^1\) Note that usually an additive constant is included in the definition of \(c\)-competitiveness, i.e., in (1) and (2). However, for the problems we consider, this changes the advice complexity by at most \(O(\log n)\); see Remark 9 in Boyar et al. \[7\].
information content of the given problem [12]. Moreover, there is a non-trivial connection to randomized online algorithms [3,13]. Lower bounds from advice complexity often translate to lower bounds for semi-online algorithms. Essentially, here one studies whether knowing some small parameter of an online problem (such as the length of the input or the number of requests of a certain type) results in a much better competitive ratio. Lower bound results using advice can often help to answer this question. Similarly, lookahead can be seen as a special kind of advice that is supplied to an algorithm. This way, online algorithms with advice generalize a number of concepts introduced to give online algorithms more power. However, the main question posed is how much any kind of (computable) information could help; and maybe even more importantly, which amount of information will never help to overcome some certain threshold, no matter what this information actually is.

Organization, Related Work, and Results

We are mainly concerned with proving lower bounds of the form that a particular number of advice bits is necessary in order to obtain some certain output quality for a given hereditary property. We make heavy use of online reductions between generic problems and the studied ones that allow to bound the number of advice bits necessary from below. Emek et al. [11] used this technique in order to prove lower bounds for metrical task systems. The foundations of the reductions as we perform them here are due to Böckenhauer et al. [2], who introduced the string guessing problem, and Boyar et al. [7], who studied a problem called asymmetric string guessing. Mikkelsen [20] introduced a problem, which we call the anti-string guessing problem, and which is a variant of string guessing with a more “friendly” cost function. Our reductions rely on some results from Bartal et al. [1] that characterize hereditary properties by forbidden subgraphs together with some insights from Ramsey theory (see, e.g., Diestel [8]).

In Section 2, we recall some basic results from Ramsey theory and define the generic online problems that we use as a basis of our reductions. In Section 3, we study both MAX-\(\pi\) and MIN-\(\pi\) in the case that no preemption is allowed; using a reduction from the asymmetric string guessing problem, we show that any \(c\)-competitive online algorithm for MAX-\(\pi\) needs roughly \(n/c\) advice bits, and this is essentially tight. This complements the results from Bartal et al. [1] stating that, without any advice, even a randomized algorithm cannot achieve a competitive ratio better than \(\Omega(n^{1-\log_4 3-o(1)})\). The advice complexity of the maximum independent set problem on bipartite and sparse graphs was studied by Dobrev et al. [10]. In the subsequent sections, we allow the online algorithm to use preemption. In Section 4, we use a reduction from the string guessing problem to show a lower bound of \(\Omega(n/(c^2 \log c))\) on the number of the bits of advice that are needed to obtain competitive ratio \(c\), where \(c\) is any increasing function bounded from above by \(\sqrt{n/\log n}\). In Section 5, using a reduction from the anti-string guessing problem, we also give a linear lower bound for \(c\) being close to 1.

Due to space constraints, some of the proofs are omitted.

2 Preliminaries

Hereditary properties can be characterized by forbidden induced subgraphs as follows: if a graph \(G\) does not satisfy a hereditary property \(\pi\), then any graph \(H\) such that \(G\) is an induced subgraph of \(H\) does not satisfy \(\pi\) neither. Hence, there is a (potentially infinite) set of minimal forbidden graphs (w.r.t. being induced subgraph) \(S_\pi\) such that \(G\) satisfies \(\pi\) if and only if no graphs from \(S_\pi\) are induced subgraphs of \(G\). Conversely, any set of graphs \(S\) defines a hereditary property \(\pi_S\) of not having a graph from \(S\) as induced subgraph.
Furthermore, there is the following bijection between hereditary and cohereditary properties: for a hereditary property $\pi$ we can define a property $\pi^c$ such that a graph $G$ satisfies $\pi$ if and only if it does not satisfy $\pi^c$ (it is easy to see that $\pi^c$ is cohereditary), and vice versa. Hence, a cohereditary property $\pi$ can be characterized by a set of minimal (w.r.t. being induced subgraph) obligatory subgraphs $S_\pi$ such that a graph $G$ has the property $\pi$ if and only if at least one graph from $S_\pi$ is an induced subgraph of $G$.

To each property $\pi$ we can define the complementary property $\pi^c$ such that a graph $G$ satisfies $\pi^c$ if and only if the complement of $G$ satisfies $\pi$. Clearly, if $\pi$ is (co)hereditary, so is $\pi^c$. Moreover, if $H$ is forbidden (obligatory, respectively) for $\pi$, $\overline{H}$ is forbidden (obligatory, respectively) for $\pi^c$. The following statement is due to Lewis and Yannakakis.

Lemma 1 (Lewis and Yannakakis [15], proof of Theorem 4). Every non-trivial hereditary property $\pi$ is satisfied either by all cliques or by all independent sets.

Proof. Assume, for the sake of contradiction, that there is a hereditary property $\pi$, and two numbers $m$, $n$, such that $K_m$ and $K_n$ do not satisfy $\pi$. Let $r(m,n)$ be the Ramsey number [17], such that every graph with at least $r(m,n)$ vertices contains $K_m$ or $\overline{K}_n$ as induced subgraph. Since $\pi$ is non-trivial, there is a graph $G$ with more than $r(m,n)$ vertices that satisfies $\pi$. $G$ contains either $K_m$ or $\overline{K}_n$ as induced subgraph, and since $\pi$ is hereditary, either $K_m$ or $\overline{K}_n$ satisfies $\pi$.

Bartal et al. proved the following theorem. It is formulated in the known supergraph model, where a graph $G = (V,E)$ with $n$ vertices is a-priori known to the algorithm, and the input is a sequence of vertices $v_1, \ldots, v_k$. The task is to select in an online manner the subgraph of the induced graph $G[v_1, \ldots, v_k]$ having property $\pi$.

Theorem 2 (Bartal et al. [1] and references therein). In the known supergraph model, any randomized algorithm for the MAX-$\pi$ problem has competitive ratio

$$\Omega\left(n^{1-\log_4 3-o(1)}\right),$$

even if preemption is allowed.

Note that $n$ in the previous theorem thus refers to the size of the known supergraph, and not to the length of the input sequence. However, in the proof a graph with $n = 4^i$ vertices is considered, from which subgraphs of size $3^i$ are presented. Each of these instances has an optimal solution of size at least $2^i$, and it is shown that any deterministic algorithm can have a profit of at most $\alpha(3/2)^i \log n$ on average, for some constant $\alpha$. From that, using Yao’s principle [19] as stated in [6], the result follows. The same set of instances thus yields the following result.

Theorem 3 (Bartal et al. [1]). Any randomized algorithm for the MAX-$\pi$ problem has competitive ratio

$$\Omega\left(n^{2/\log_3 3-o(1)}\right),$$

even if preemption is allowed.

Next, we describe some specific online problems that allow us to give lower bounds on the advice complexity using a special kind of reduction. Böckenhauer et al. [2] introduced a very generic online problem called string guessing with known history over alphabets of size $\sigma$ ($\sigma$-SGKH). The input is a sequence of requests $(x_0, \ldots, x_n)$ where $x_0 = n$ and for
i ≥ 1, x_i ∈ \{1, \ldots, \sigma\}. The algorithm has to produce a sequence of answers (y_1, \ldots, y_n, y_{n+1}), where y_i ∈ \{1, \ldots, \sigma\} and y_{n+1} = \perp and where y_i is allowed to depend on x_0, \ldots, x_{i-1} (and of course any advice bits the algorithm reads). The cost is the number of positions \(i\) for which \(y_i \neq x_i\).

Theorem 4 (Böckenhauer et al. [2]). Let \(\sigma \geq 2\). Any online algorithm with advice for \(\sigma\)-SGKH that guesses \(\gamma n\) bits of the input correctly must read at least
\[
\left(1 + (1 - \gamma) \log_\sigma \left(\frac{1 - \gamma}{\sigma - 1}\right) + \gamma \log_\sigma \gamma\right) n \log_2 \sigma
\]
advice bits.

Mikkelsen [20] introduced the problem anti-string guessing with known history over alphabets of size \(\sigma\) (anti-\(\sigma\)-SGKH). It is defined exactly as \(\sigma\)-SGKH except that the cost is the number of positions \(i\) for which \(y_i = x_i\).

Theorem 5 (Mikkelsen [20, Theorem 11]). Let \(\sigma \geq 2\) and let \(1 \leq c < \sigma/(\sigma - 1)\). Any \(c\)-competitive anti-\(\sigma\)-SGKH algorithm must read at least
\[
\left(1 - h_\sigma \left(\frac{1}{c}\right)\right) n \log_\sigma \sigma
\]
bits of advice, where \(n\) is the input length. This holds even if \(n\) is known in advance. Here, \(h_\sigma\) is the \(\sigma\)-ary entropy function given by \(h_\sigma(x) = x \log_\sigma (\sigma - 1) - x \log_\sigma x - (1-x) \log_\sigma (1-x)\).}

Boyar et al. [7] investigated a problem called maximum asymmetric string guessing (MAXASGk). The input is a sequence of requests \((x_0, \ldots, x_n)\) where \(x_0 = \perp\) and for \(i \geq 1\), \(x_i \in \{0, 1\}\). The algorithm has to produce a sequence of answers \((y_1, \ldots, y_n, y_{n+1})\). The output is feasible if \(x_i \leq y_i\) for all \(1 \leq i \leq n\). The profit of the algorithm is the number of zeros in \(y_1, \ldots, y_n\) for feasible outputs, and \(-\infty\) otherwise. The “blind” version of the problem, where the algorithm has to produce the outputs without actually seeing the requests (i.e., in each step, the algorithm receives some dummy request \(\perp\)), is denoted MAXASGU. In what follows, let
\[
B_c := \log \left(1 + \frac{(c - 1)c^{c-1}}{c^c}\right) \approx \frac{1}{c} \cdot \frac{1}{e \ln 2}\.
\]

Theorem 6 (Boyar et al. [7]). For any function \(c(n)\) such that \(1 \leq c(n) \leq n\), there is a \(c\)-competitive algorithm for MAXASGk (MAXASGU, respectively) with advice of size \(B_c \cdot n + O(\log n)\). Moreover, any \(c\)-competitive algorithm for MAXASGk (MAXASGU, respectively) must read at least
\[
B_c \cdot n - O(\log n)
\]
bits of advice.

Note that in general, it does not make much difference if the length of the input is initially known to the algorithm or not. More specifically, it changes the advice complexity by at most \(O(\log n)\).

3 Max-\(\pi\) and Min-\(\pi\) without Preemption

First, we show that for any non-trivial hereditary property \(\pi\), the MAX-\(\pi\) problem is equivalent to the asymmetric string guessing in the following sense.
Theorem 7. If there is a c-competitive algorithm for MAXASGU, then there is a c-competitive algorithm for MAX-Π using the same advice.

Theorem 8. If there is a c-competitive algorithm for MAX-Π that reads b(n) bits of advice, then there is a c-competitive algorithm for MAXASGK using

\[ b(n) + O(\log^2 n) \]

bits of advice.

Before proving Theorem 8, let us recall Lemma 3 from Bartal et al. [1].

Lemma 9 (Bartal et al. [1]). Given any graph \( H \), there exist constants \( n_0 \) and \( \alpha \) such that for all \( n > n_0 \) there exists a graph \( G \) on \( n \) vertices such that any induced subgraph of \( G \) on at least \( \alpha \log n \) vertices contains \( H \) as an induced subgraph.

This is a variant of Lemma 9 from Lund and Yannakakis [16].

Lemma 10 (Lund and Yannakakis [16]). Let \( H \) be a graph on \( k \) vertices. For sufficiently large \( N \), for any graph \( G \) on \( N \) vertices and for all \( \ell = \Omega(\log N) \), a random subgraph \( G' \) of \( G \) does not, with probability 1/2, contain a subset \( S \) of \( \ell \) vertices that is a clique in \( G \) but \( H \) is not an induced subgraph of \( G'[S] \).

Proof of Theorem 8. According to Lemma 1, \( \pi \) is satisfied either by all cliques or by all independent sets. Without loss of generality, suppose the latter (otherwise, swap the edges and non-edges in the following arguments).

Consider a binary string \( \nu = x_1, \ldots, x_n \) (for large enough \( n \)). Let us consider the graph \( G_\nu = (V,E) \) defined as follows. Let \( H \) be an arbitrary but fixed forbidden subgraph of \( \pi \). Let \( G' \) be the \( n \)-vertex graph from Lemma 9 with vertices \( V = \{v_1, \ldots, v_n\} \). If \( x_i = 0 \) for some \( i \), delete from \( G' \) all edges \( \{v_i, v_j\} \) for \( j > i \). In the graph \( G_\nu \) thus defined, the vertices \( v_i \) for which the corresponding \( x_i \) satisfies \( x_i = 0 \) (denoted by \( I_\nu \subseteq V \) in the sequel) form an independent set, and hence \( G_\nu[I_\nu] \) has property \( \pi \). On the other hand, any induced subgraph \( G_\nu[S] \) with property \( \pi \) can contain at most \( \alpha \log n \) vertices from \( V \setminus I_\nu \) (otherwise it would contain the forbidden graph \( H \) as induced subgraph). Note that, with \( O(\log n) \) bits of advice to encode \( n \), the graph \( G_\nu \) can be constructed from the string \( \nu \) in an online manner: the base graph \( G' \) is fixed for a fixed \( n \), and the subgraph \( G_\nu[v_1, \ldots, v_i] \) depends only on the values of \( x_1, \ldots, x_{i-1} \).

Now let us consider a \( c \)-competitive algorithm \( \text{ALG}_\pi \) for MAX-Π that uses \( b \) bits of advice. Let us describe how to derive an algorithm \( \text{ALG} \) for MAXASGK from \( \text{ALG}_\pi \). For a given string \( \nu = x_1, \ldots, x_n \), where \( \perp, x_1, \ldots, x_n \) is the input for MAXASGK, the advice for \( \text{ALG} \) consists of three parts: first, there is a self-delimited encoding of \( n \) using \( O(\log n) \) bits, followed by a (self-delimited) correction string \( e_\nu \) of length \( O(\log^2 n) \) bits described later, and the rest is the advice for \( \text{ALG}_\pi \) on the input \( G_\nu \). Let \( S \) be the solution (set of vertices) returned by \( \text{ALG}_\pi \) on \( G_\nu \) (with the proper advice). As argued before, \( S \) can contain at most \( \alpha \log n \) vertices from \( V \setminus I_\nu \). The indices of these vertices from \( S_{\text{out}} := S \cap (V \setminus I_\nu) \) are part of the string \( e_\nu \). Apart from that, \( e_\nu \) contains the indices of at most \( \alpha \log n \) vertices \( S_{\text{in}} \subseteq I_\nu \) such that \( |(S \setminus S_{\text{out}}) \cup S_{\text{in}}| = \min\{|S|, |I_\nu|\} \).

The algorithm \( \text{ALG} \) works as follows: at the beginning, it constructs the graph \( G' \). When a request \( x_i \) arrives, \( \text{ALG} \) sends the new vertex \( v_i \) of \( G_\nu \) to \( \text{ALG}_\pi \), and finds out whether

---

2 Note that the original lemma speaks about pseudo-random subgraphs, which is a stronger assumption that we do not need here.
$v_i \in S$. If $v_i \in S_{in}$, ALG answers 0 regardless of the answer of ALG$_\pi$. Similarly, if $v_i \in S_{out}$, ALG answers 1. Otherwise, ALG answers 0 if and only if $v_i \in S$.

First note that ALG always produces a feasible solution: if the input $x_i = 1$ then either $v_i \notin S$, and ALG returns $y_i = 1$, or else $v_i$ is included in $S_{out}$. Moreover, the number of zeros (the profit) in the output of ALG is $\min\{|S|, |I_\nu|\}$, where $|I_\nu|$ is the profit of the optimal solution. Since ALG$_\pi$ is $c$-competitive, $|S| \geq (1/c) \cdot \text{profit}(\text{OPT}(G_\nu)) \geq (1/c) \cdot |I_\nu|$.

**Corollary 11.** Let $\pi$ be any non-trivial hereditary property. Let $A_{c,n}$ be the minimum advice needed for a $c$-competitive Max-$\pi$ algorithm. Then

$$B_c \cdot n - O(\log^2 n) \leq A_{c,n} \leq B_c \cdot n + O(\log n).$$

We have shown that the advice complexity of Max-$\pi$ essentially does not depend on the choice of the property $\pi$. Interestingly, this is not the case with cohereditary properties and Min-$\pi$. On one hand, there are cohereditary properties where little advice is sufficient for optimality as the following theorem shows.

**Theorem 12.** If a cohereditary property $\pi$ can be characterized by finitely many obligatory subgraphs, there is an optimal algorithm for Min-$\pi$ with advice $O(\log n)$.

**Proof.** Since each obligatory subgraph has constant size, $O(\log n)$ bits can be used to encode the indices of the vertices (forming the smallest obligatory subgraph) that are included in an optimal solution.

On the other hand, there are properties for which Min-$\pi$ requires large advice as stated by the following theorem, which was proven by Boyar et al. [7]. The problem minimum cycle finding requires to identify a smallest possible set of vertices $S$ such that $G[S]$ contains a cycle. Hence, it is the Min-$\pi$ problem for the non-trivial cohereditary property “contains cycle.”

**Theorem 13 (Boyar et al. [7]).** Any $c$-competitive algorithm for the minimum cycle finding problem must read at least

$$B_c \cdot n - O(\log n)$$

bits of advice.

An upper bound analogous to Theorem 7 also follows from the results of Boyar et al. [7]; note that, for the minimum cycle finding problem, this bound is tight up to an additive constant of $O(\log n)$.

**Theorem 14.** Let $\pi$ be any non-trivial cohereditary property. There is a $c$-competitive algorithm for Min-$\pi$ which reads

$$B_c \cdot n + O(\log n)$$

bits of advice.

## 4 Max-$\pi$ with Preemption – Large Competitive Ratios

In this and the subsequent section, we consider the problem Max-$\pi$ with preemption where $\pi$ is a non-trivial hereditary property. In every time step, an online algorithm can either accept or reject the currently given vertex and preempt any number of vertices that it
accepted in previous time steps. However, vertices that were once rejected or preempted cannot be accepted in later time steps. The goal is to accept as many vertices as possible. After each request, the solution is required to have the property $\pi$.\footnote{Note that without preemption, the condition to maintain $\pi$ in every time step is implicit. Indeed, if $\pi$ is violated in some step, it means that the algorithm has accepted a forbidden subgraph, which means that no matter how the sequence continues, the solution will ultimately be invalid. Let us emphasize that any algorithm that worked for the case without preemption also works with preemption.} Using a string guessing reduction, we can prove the following theorem; due to space constraints, we only give the idea.

\textbf{Theorem 15.} Consider the MAX-$\Pi$ problem with preemption, for a hereditary property $\pi$ with a forbidden subgraph $H$, such that $\pi$ holds for all independent sets. Let $c(n)$ be an increasing function such that $c(n) \log c(n) = o(\sqrt{n/\log n})$. Any $c(n)$-competitive MAX-$\Pi$ algorithm must read at least

$$\Omega\left(\frac{n}{c(n)^2 \log c(n)}\right)$$

bits of advice.

\textbf{Proof Sketch.} First, for some given $n$ and $\sigma$, let us define the graph $G_{n,\sigma}$ that will be used in the reduction. To ease the presentation, assume that $n' = n/\sigma$ is integer. Let $G_1$ be a graph with $\sigma$ vertices, the existence of which is asserted by Lemma 9, such that any subgraph of $G_1$ with at least $\kappa_1 \log \sigma$ vertices contains $H$ as induced subgraph. Let $G_B$ be the complement of a union of $n'$ cliques of size $\sigma$ (i.e., $G_B$ consists of $n'$ independent sets $V_1, \ldots, V_{n'}$ of size $\sigma$, and all remaining pairs of vertices are connected by edges). Applying Lemma 10 to $G_B$ proves an existence of a graph $G_2 \subseteq G_B$ such that any subset of $G_2$ with at least $\kappa_2 \log n$ vertices contains $H$ as an induced subgraph. The graph $G_{n,\sigma}$ is obtained from $G_2$ by replacing each independent set $V_i$ with a copy of $G_1$ (each such copy is called a “layer” in what follows).

Let us suppose that a $c(n)$-competitive MAX-$\Pi$ algorithm $\text{ALG}$ is given that uses $\mathcal{S}(n)$ advice bits on instances of size $n$. Now fix an arbitrary $n$, and choose $\sigma := 4ck_1 \log(4ck_1)$. We show how to solve instances of $\sigma$-SGKH of length $n' - 1$ using $\text{ALG}$. Let $q_1, \ldots, q_{n'-1}$ be the instance of $\sigma$-SGKH, where $q_i \in \{1, \ldots, \sigma\}$. The corresponding instance $G$ for the MAX-$\Pi$ problem is as follows: take the graph $G_{n,\sigma}$, and denote by $v_{i,1}, \ldots, v_{i,\sigma}$ the vertices of the set $V_i$. Let $v_{i,q_i}$ be the distinguished vertex in set $V_i$. Delete from $G_{n,\sigma}$ all edges of the form $(v_{i,q_i}, v_{i',q_i'})$ where $i' > i$. The resulting graph $G$ is presented to $\text{ALG}$ in the order $v_{1,1}, \ldots, v_{1,\sigma}, v_{2,1}, \ldots, v_{2,\sigma}, \ldots$

Note that $G$ can be constructed online based on the instance $q_1, \ldots, q_{n'-1}$. The distinguished vertices form an independent set of size $n'$, and thus a feasible solution. On the other hand, apart from the distinguished vertices, any solution can have at most $\kappa_1 \log \sigma$ vertices in one layer (otherwise there would be a forbidden subgraph in that layer), and at most $\kappa_2 \log n$ layers with vertices other than the distinguished one (if there are more than $\kappa_2 \log n$ nonempty layers, choose one vertex from each nonempty layer; these form a clique in $G_B$, and due to Lemma 10 induce $H$ in $G_2$, and thus also in $G$). Hence, $n' \leq \text{profit}(\text{Opt}(G)) \leq n' + K$, where $K := \kappa_1 \kappa_2 \log \sigma \log n$.

Since $\text{ALG}$ is $c$-competitive, it produces a solution of size at least $\text{profit}(\text{Opt}(G))/c$. Since any solution can have at most $K$ non-distinguished vertices, the solution of $\text{ALG}$ contains at least $g := \text{profit}(\text{Opt}(G))/c - K$ distinguished vertices.
Consider an algorithm ALG’ for $\sigma$-SGKH of length $n’ - 1$, which simulates ALG: for the $i$th request, it presents ALG with the layer of vertices $V_i$. Let Cand$(i) \subseteq V_i$ (the candidate set) be the set of vertices selected by ALG from $V_i$. As stated before, $|\text{Cand}(i)| \leq \kappa_1 \log \sigma$. A set Cand$(i)$ is good if it contains the distinguished vertex $v_{i,q}$. It follows from the definition of the problem that there are at least $g$ good candidate sets.

ALG’ uses an additional $O(\log \log \sigma)$ bits of advice to describe a number $j$, $1 \leq j \leq \kappa_1 \log \sigma$, and selects the $j$th vertex from any Cand$(i)$ as an answer (if |Cand$(i)$| is smaller than $j$, it is extended in an arbitrary fixed way). The number $j$ is selected in such a way that ALG’ gives the correct answer from a fraction of $1/(\kappa_1 \log \sigma)$ of good sets. Putting it together, the fraction of correctly guessed numbers by ALG’ is at least

$$\alpha := \frac{n’ - cK}{cK_1 \log \sigma(n’ - 1)}.$$ 

Note that $1/(\kappa_1 \log \sigma) \geq \alpha \geq 1/(2cK_1 \log \sigma)$ holds for large enough $n$, provided that $n’ \geq 2cK - 1$. To see that this inequality holds, note that

$$n’ \geq 2cK - 1 \iff \frac{n}{4cK_1 \log(4cK_1)} \geq 2cK - 1 \iff (2cK - 1)4cK_1 \log(4cK_1) \leq n.$$ 

The last inequality holds for large enough $n$ by the choice of $c(\cdot)$ due to the fact that

$$(2cK - 1)4cK_1 \log(4cK_1) = O(c(n)^2 K \log c(n)) = O((c(n) \log c(n))^2 \log n) = o(n).$$

Due to Theorem 4, any algorithm for $\sigma$-SGKH that correctly guesses a fraction of $\alpha$ numbers (for $1/\sigma \leq \alpha \leq 1$) on an input of length $n’ - 1$ requires at least $S := F(\sigma, \alpha) \cdot (n’ - 1) \cdot \log_2 \sigma$ bits of advice where

$$F(\sigma, \alpha) := 1 + (1 - \alpha) \log_\sigma \left(\frac{1 - \alpha}{\sigma - 1}\right) + \alpha \log_\sigma \alpha.$$ 

It can be shown that $F(\sigma, \alpha) \log \sigma = \Omega(1/c)$. Finally, the theorem follows by noting that

$$n’ - 1 = \Omega(n/(c \log c)).$$

Using a similar approach, we can get a stronger bound for the independent set problem.

**Theorem 16.** Let $c(n)$ be any function such that

$$8 \leq c(n) \leq \frac{1 + \sqrt{1 + 4n}}{4}.$$ 

Any $c(n)$-competitive independent set algorithm that can use preemption must read at least

$$A_{c,n} \geq \frac{0.01 \cdot \log(2c)}{2c^2} (n - 2c)$$

advice bits.

5 **Max-$\pi$ with Preemption – Small Competitive Ratios**

In this section, we use Theorem 5 to give bounds on small constant values of the competitive ratio for algorithms for Max-$\pi$ complementing the bounds from Theorem 15. In what follows, $\pi$ is a non-trivial hereditary property and $k$ is the size of a smallest forbidden subgraph according to $\pi$. 
Theorem 17. If there is a c-competitive algorithm for MAX-$\Pi$ with preemption that reads $b(kn)$ bits of advice for inputs of length $kn$, then there exists a c-competitive algorithm for Anti-$k$-SGKH, which, for inputs of length $n$, reads

$$b(kn) + O(\log^2 n)$$

bits of advice.

Proof. According to Lemma 1, $\pi$ is satisfied either by all cliques or by all independent sets. We assume in the following, that $\pi$ is satisfied by all independent sets (if it is not, we can use the same argument by swapping edges and non-edges between layers). We describe how to transform an instance of Anti-$k$-SGKH into an instance of MAX-$\Pi$ with preemption. The length of the instance for MAX-$\Pi$ with preemption will be $k$ times as long as the length $n$ of the Anti-$k$-SGKH instance. We proceed to show that a c-competitive algorithm for the latter implies a c-competitive algorithm for the former which reads at most $O((\log n)^2)$ additional advice bits.

Let $\nu = x_1, \ldots, x_n$ (with $x_i \in \{1, \ldots, k\}$ be an instance of Anti-$k$-SGKH. Consider the $n$-vertex graph $\tilde{G} = (V(\tilde{G}), E(\tilde{G}))$, given by Lemma 9 for a size-$k$ smallest minimal forbidden subgraph $H = (V(H), E(H))$ from $\pi$. We recall that any induced subgraph of $\tilde{G}$ with at least $\alpha \log n$ vertices contains $H$ as an induced subgraph. Let us denote $V(\tilde{G}) = \{\tilde{v}_1, \ldots, \tilde{v}_n\}$ and $V(H) = \{h_1, \ldots, h_k\}$. We now describe the construction of a graph $G_\nu = (V(G_\nu), E(G_\nu))$, which will be the input for the given algorithm for MAX-$\Pi$. To this end, let

$$V(G_\nu) = \bigcup_{i=1}^{n} \bigcup_{j=1}^{k} v^i_j,$$

$$E(G_\nu) = \{\{v^i_j, v^i_{j'}\} | \{h_j, h_{j'}\} \in E(H)\} \cup \{\{v^i_j, v^{i'}_{j'}\} | i < i', \{\tilde{v}_j, \tilde{v}_{j'}\} \in E(\tilde{G}), j \neq x_i\},$$

where we assume an ordering $v^1_1, v^1_2, \ldots, v^1_k, v^2_1, \ldots, v^n_k$ on the vertices. Moreover, we denote the requests $v^i_1, \ldots, v^i_k$ as layer $i$. Let $X$ denote the set of vertices $v^i_{x_i}$ for $i = 1, \ldots, n$.

We start with a few observations about $G_\nu$ that are straightforward.

Observation 1. $G_\nu[X]$ is an independent set of size $n$. In particular, it has property $\pi$.

Observation 2. $G_\nu[v^i_1, \ldots, v^i_k] = H$ for an arbitrary but fixed $i$. Thus, any induced subgraph of $G_\nu$ that contains $G_\nu[v^i_1, \ldots, v^i_k]$ not does not have property $\pi$.

Observation 3. Consider a set of vertices, $V$, in $G_\nu$ which is disjoint from $X$. If $|V| \geq k\alpha \log n$, then $G_\nu[V]$ does not have property $\pi$.

Note that $V$ must in this case contain vertices from at least $\alpha \log n$ different layers. These have $H$ as an induced subgraph since none of them are in $X$.

Now consider a c-competitive algorithm $\text{Alg}_\Pi$ for MAX-$\Pi$ with preemption reading $b(kn)$ bits of advice (recall that $kn$ is the length of its input $G_\nu$). We start by describing an algorithm $\text{Alg}'$ for Anti-$k$-SGKH, which uses $b(kn)$ bits of advice ($n$ is the length of its input). Afterwards, we use it to define another algorithm $\text{Alg}$ for Anti-$k$-SGKH, which uses $O((\log^2 n)$ additional advice bits and is c-competitive.

For a given string $\nu = x_1, \ldots, x_n$, let $\perp, x_1, \ldots, x_n$ be the input for Anti-$k$-SG. Let $S$ be the solution (set of vertices) returned by $\text{Alg}_\Pi$ on $G_\nu$ (with the proper advice). Note that this is the resulting set of vertices after the unwanted vertices have been preempted. $\text{Alg}'$ works as follows: It constructs the graph $G_\nu$ online and simulates $\text{Alg}_\Pi$ on it. When a request $i$ arrives, the goal of $\text{Alg}'$ is to guess a number in $\{1, \ldots, k\}$ different from $x_i$. 

It does this by presenting all vertices in layer $i$ to $\text{ALG}_\pi$. It is important to note that the vertices in layer $i$ can be presented without knowledge of $x_1, \ldots, x_n$. Let $S_i$ denote the set of these vertices, which are accepted by $\text{ALG}_\pi$ and have not been preempted after request $v^i_k$. In layer $i$, $\text{ALG}'$ outputs $y_i = w$ where $w$ is the smallest number in $\{1, \ldots, k\}$ such that $v^i_w \notin S_i$. Note that such a number always exists because of Observation 2.

We now describe $\text{ALG}$, which uses $O(\log^2 n)$ additional advice bits. The advice for $\text{ALG}$ consists of three parts: First, a self-delimiting encoding of $n$ (this requires $O(\log n)$ bits). This is followed by a list of up to $k\alpha \log n$ indices $i$, where $\text{ALG}'$ outputs $y_i = x_i$. Let $S_{\text{error}}$ denote the set of these indices. A self-delimiting encoding of this requires $O(\log^2 n)$ bits (recall that $\alpha$ and $k$ are constant). Finally, the advice which $\text{ALG}'$ received is included. This is $\mathcal{b}(kn)$ bits.

$\text{ALG}$ works as follows for each request: If the request is not in $S_{\text{error}}$, it outputs the same as $\text{ALG}'$. Conversely, if the request is in $S_{\text{error}}$, it outputs another number in $[k]$.

We now argue that $\text{ALG}$ is $c$-competitive. We note that the optimal offline solution to $\text{MAX-}\pi$ on $G_\nu$ contains at most $k\alpha \log n$ vertices not in $X$. The same of course holds for the solution produced by $\text{ALG}_\pi$. Moreover, it holds that if in layer $i$ the algorithm $\text{ALG}_\pi$ accepts a vertex in $X$, then $\text{ALG}'$ outputs $y_i \neq x_i$. This means that the score of $\text{ALG}_\pi$ is at most $k\alpha \log n$ more than the score of $\text{ALG}'$. Since the score of $\text{ALG}$ is $k\alpha \log n$ more than the score of $\text{ALG}'$, we have that $\text{ALG}$ is $c$-competitive.

Combining Theorems 5 and 17, we get the following corollary.

\begin{corollary}
For a non-trivial hereditary property, $\pi$, with a minimal forbidden subgraph of size $k$, the following holds: Let $1 < c < k/(k-1)$. Any $c$-competitive algorithm for $\text{MAX-}\pi$ with preemption must read at least
\[
\left(1 - h_k \left(\frac{1}{c}\right)\right) \frac{n \log k}{k} - O(\log^2 n)
\]
bits of advice, where $n$ is the input length. Here, $h_k$ is the $k$-ary entropy function given by $h_k(x) = x \log_k (k - 1) - x \log_k x - (1 - x) \log_k (1 - x)$.
\end{corollary}

\section{Closing Remarks}

In Corollary 11, we describe lower and upper bounds for the advice complexity of all online hereditary graph problems, which are essentially tight (there is just a gap of $O(\log^2 n)$). It turns out that, for all of them, roughly the same amount of information about the future is required to achieve a certain competitive ratio.

Intriguingly, we see quite a different picture for cohereditary properties. Theorem 14 gives the same upper bound as we had for hereditary properties, and Theorem 13 shows that this upper bound is essentially tight. However, Theorem 12 shows that there exist cohereditary problems that have an advice complexity as low as $O(\log n)$ bits to be optimal. It remains open if it is only those problems with a finite set of obligatory graphs that have this very low advice complexity, or if this can also happen for cohereditary problems with an infinite set of obligatory graphs.

For hereditary problems with preemption, we show that to achieve a competitive ratio strictly smaller than $k/(k-1)$, a linear number of advice bits is needed. This is asymptotically tight, since optimality (even without preemption) can be achieved with $n$ bits. Furthermore, we show a lower bound for non-constant competitive ratios (that are roughly smaller than $\sqrt{n}$). It remains open if there is an algorithm for the preemptive case, which uses fewer advice bits than the algorithms solving the same problem in the non-preemptive case.
