Abstract

Alport syndrome results from mutations in the COL4A5 (X-linked) or COL4A3/COL4A4 (recessive) genes. This study examined 754 previously unpublished variants in these genes from individuals referred for genetic testing in 12 accredited diagnostic laboratories worldwide, in addition to all published COL4A5, COL4A3 and COL4A4 variants in the LOVD databases. It also determined genotype-phenotype correlations for variants where clinical data were available. Individuals were referred for genetic testing where Alport syndrome was suspected clinically or on biopsy (renal failure, hearing loss, retinopathy, lamellated glomerular basement membrane), variant pathogenicity was assessed using currently accepted criteria, and variants were examined for gene location, and age at renal failure onset. Results were compared using Fisher’s exact test (DNA Stata). Altogether 754 new DNA variants were identified, an increase of 25%, predominantly in people of European background. Of the 1168 COL4A5 variants, 504 (43%) were missense mutations, 273 (23%) splicing variants, 73 (6%) nonsense mutations, 169 (14%) short deletions and 76 (7%) complex or large deletions. Only 135 of the 432 Gly residues in the collagenous sequence were substituted (31%), which means that fewer than 10% of all possible variants were randomly distributed but more common at the 70 CpG sequences (p<10^-41 and p<0.001 respectively). Gly>Ala substitutions were underrepresented in all three genes (p<0.0001) probably because of an association with a milder phenotype. The average age at end-stage renal failure was the same for all mutations in COL4A5 (24.4 ±7.8 years), COL4A3 (23.3 ± 9.3) and COL4A4 (25.4 ± 10.3) (COL4A5 and COL4A3, p = 0.45; COL4A5 and COL4A4, p = 0.93).
0.55; COL4A3 and COL4A4, p = 0.41). For COL4A5, renal failure occurred sooner with non-missense than missense variants (p < 0.01). For the COL4A3 and COL4A4 genes, age at renal failure occurred sooner with two non-missense variants (p = 0.08, and p = 0.01 respectively). Thus DNA variant characteristics that predict age at renal failure appeared to be the same for all three Alport genes. Founder mutations (with the pathogenic variant in at least 5 apparently unrelated individuals) were not necessarily associated with a milder phenotype. This study illustrates the benefits when routine diagnostic laboratories share and analyse their data.

Introduction

Alport syndrome is the commonest cause of inherited renal failure after polycystic kidney disease [1]. It affects at least one in 10,000 individuals and is characterised by progressive kidney failure, hearing loss, and ocular abnormalities [2]. Inheritance is X-linked with COL4A5 mutations [3] in 85% of cases and autosomal recessive with COL4A3 or COL4A4 mutations in most of the others [4,5]. Individuals with heterozygous COL4A3 or COL4A4 mutations usually have Thin basement membrane nephropathy with normal renal function [6,7,8] but some develop renal impairment [9].

The clinical features in Alport syndrome are explained because the COL4A5 and COL4A3/ COL4A4 genes code for the collagen IV α5 chain, α3 and α4 chains which form a heterotrimer in the basement membranes of the glomerulus, cochlea and eye [10] (Table 1). Each collagen IV chain has non-collagenous amino and carboxy termini, and an intermediate collagenous domain with Gly-X-Y, with multiple short non-collagenous interruptions [10]. Glycine is found at each third residue in the collagen sequence and is critical for triple helix formation.

The ‘Expert guidelines on the diagnosis and management of Alport syndrome’ [2] recommend that all individuals with likely Alport syndrome should undergo genetic testing, to confirm the diagnosis and mode of inheritance, and predict the age at renal failure. The Guidelines also recommend cases of suspected Thin basement membrane nephropathy undergo genetic testing when it is important to exclude X-linked Alport syndrome [2].

Mutations in the COL4A5, COL4A3 and COL4A4 genes are mainly nonsense or missense. Genotype-phenotype correlations have only been characterised for X-linked disease [11,12,13]. Nonsense mutations are typically associated with early onset renal failure (before 30), lenticonus and central retinopathy. Deletions and insertions often cause a frameshift, and downstream nonsense variant. Many missense mutations result in a milder phenotype with later onset renal failure without ocular features [11,12,13,14].

The commonest method used currently for mutation detection is whole exome sequencing (WES). The widespread adoption of WES together with the Exome Aggregation Consortium (ExAc collaboration, http://exac.broadinstitute.org/, the ‘1000 genomes’, http://1000genomes.org/ and Hapmap, https://hapmap.ncbi.nlm.nih.gov/, projects), have greatly increased the number of reported pathogenic and normal DNA variants [15].

Collecting all pathogenic and normal variants for each disease-related gene in a publicly-accessible variant database avoids the duplication involved in assessing pathogenicity, and improves the speed and accuracy of testing while limiting cost.

The present study has reviewed known variants in the Alport genes, including 754 recently-submitted from members of the Alport mutation database Consortium to the publicly-accessible LOVD databases, with the aims of further characterising DNA variants, and genotype-phenotype correlations. The LOVD databases continue to be updated.
Methods
Assembly of the variants

DNA variants were extracted from the literature, from other databases (eg ARUP) or from previously-unpublished deidentified submissions direct to the LOVD COL4A5, COL4A3 and COL4A4 database from contributing members of the International Alport Mutation Database Consortium in the UK and Europe, Korea, the US and Australia. Genetic testing from laboratories run by Consortium members was performed after written informed consent had been obtained by the treating clinicians. Submission of variants to the databases was undertaken with IRB approval where this was required (Northern Health HREC, IRB of Seoul National University, CEIC Fundacio Puigvert, Veltishev Pediatric Clinical Research Institute).

In general, individuals had been referred for genetic testing where Alport syndrome was suspected clinically or on renal biopsy (renal failure, hearing loss, retinopathy, lamellated glomerular basement membrane). Clinical data (age, gender, diagnosis and age at onset of renal failure, and, where known, hearing loss and ocular abnormalities) were obtained in a manner conforming with local IRB ethical guidelines according to the Declaration of Helsinki. The testing laboratory deidentified information before submission to the databases.

Variants had been collected by individual laboratories over a ten year period and mutation detection methods varied during this time. All laboratories had used Sanger sequencing at some stage, few had used MLPA, but recently most had used whole exome sequencing. Most diagnostic laboratories confirmed any variant found with WES using Sanger sequencing. All laboratories were accredited by their national board but there was no uniformity in how they confirmed variant pathogenicity. This was most often with consulting the LOVD, and recently, the ExAc databases, and sometimes using an online tool such as Alamut.

Variants were described according to the reference transcripts of COL4A5 (the longer form found in the kidney, LRG_232t2, NM_033380.2), COL4A3 (LRG_230t1, NM_000091.4) and COL4A4 (LRG_231t1, NM_000092.4) and the nomenclature guidelines of the Human Genome Variation Society (HGVS) [16]. Variant descriptions were confirmed with the Mutalyzer programme (http://mutalyzer.nl/) [17]. Pathogenicity assessments were as published or as provided by the submitting laboratory. In general these were based on the HGVS definitions [18]. Variants were not checked independently with any algorithms such as the Human Splicing Finder because their efficacy and accuracy is not confirmed in the genes of interest. Our
definition for splicing mutations included the 10 intronic nucleotides immediately adjacent to
the exon-intron boundaries. Deep intronic variants were only included where the submitting
laboratory believed them to be disease-causing.

Variants, demographic and clinical data were added to the LOVD databases that included
all published COL4A5, COL4A3 and COL4A4 variants. Disease-associated variants already
recorded in the database but from apparently unrelated families were included to identify the
prevalence of Alport syndrome and any common or founder mutations. Mode of inheritance,
gender and clinical features were noted where available.

Analysis of the LOVD COL4A5, COL4A3 and COL4A4 databases

Different variant types (deletions, insertions, short deletions, arbitrarily chosen as < than 26
bp, and splicing variants) direct or indirect nonsense mutations, missense variants (resulting in
Gly or non-Gly substitutions, pathogenic or not, and synonymous changes) were counted.
Each variant was included once only in the analysis.

Large deletions were mapped against the collagen sequence. Missense variants corrected for
exon size were compared between exons to determine any increase in variants or gaps.

In addition, COL4A5 missense mutations were tested for a preferential occurrence in CpG-
associated codons [19] (especially involving the first G of Gly) using an in-house Python script
(www.python.org). CpG sites have an increased tendency for methylcytosine to spontaneou
deaminate to thymine. CG>TG and the complementary changes have a 10 times higher muta-
tion rate than normal.

The prevalence of Gly substitutions with each of 8 other amino acids or a stop codon was
compared with the expected distribution determined from collagen codon preferences [20].

Age at onset of renal failure

The nature of mutations was correlated with early and late onset renal failure, using the criteria
already identified for COL4A5 ‘severe’ variants (copy number variants, frameshifts, nonsense
and splice site mutations). Only one age was used for the variant in each family, and for
COL4A5 variants, the ages at renal failure in males and females were studied separately. Where
several members of the same family or unrelated individuals with the same mutation were
described, the youngest age of onset of renal failure was recorded. For COL4A3 and COL4A4,
the age at end-stage renal failure in males and females were combined, and the number of
severe variants recorded as none, one or two.

Statistical analysis

Results were expressed as mean and SD, and results compared using Fisher’s exact test (DNA
Stata). A p value of less than 0.05 was considered significant, and a p values less than 0.10, a
trend.

Results

Twelve laboratories involved worldwide in mutation testing for Alport syndrome collaborated
to submit 754 novel variants (504 COL4A5, 133 COL4A3, 117 COL4A4 variants) to the LOVD
databases. These contributions increased the total number of variants in the databases by 25%
(754/2959), to 1168 unique variants for COL4A5 (1951 total), 266 for COL4A3 (518 total) and
268 for COL4A4 (490 total) (Table 2). Most variants were pathogenic, or of unknown signifi-
cance, from individuals with Alport syndrome or Thin basement membrane nephropathy.
Most were from Europeans with \(\text{COL4A5}\) variants, or were from Chinese (72 pathogenic, 12 normal), African (10, 8 normal), Hispanic (7 pathogenic) or Indian (2 normal) people.

**DNA variants in \(\text{COL4A5}\)**

The 1168 \(\text{COL4A5}\) unique variants included 76 complex mutations or deletions of more than 26 nucleotides (7%), 55 insertions (5%), 13 duplications (1%), 169 short deletions (with fewer than 26 nucleotides, 14%), and 16 indels (1%). 73 nonsense mutations (6%) and 504 missense variants (43%) and 273 (23%) splicing variants (Table 2). Uncommonly two pathogenic variants were found in the same individual (11/1168, 1%).

**Large deletions/indels/rearrangements.** There were 25 large deletions. Seven originated in \(\text{COL4A6}\) and terminated in exon 1 or the nearby intron of \(\text{COL4A5}\). Eight large deletions originated in exons 1–4. Only 9 deletions (fewer than half) had their origins after exon 4, and six at exons 37 to 41.

**Direct nonsense mutations.** There were 73 (6%) direct nonsense mutations but the insertions/deletions and duplications that result in a frameshift meant that there were potentially 402 variants producing a downstream nonsense change (34%). In addition, 17 direct stop codons resulted from Gly substitutions (4%) which matched the expected prevalence (4%) (Table 3).

**Missense mutations.** There were 504 missense variants (43%) of which 391 (33%) were Gly substitutions, and 113 (10%) non-Gly substitutions. Thus Gly in \(\text{COL4A5}\) was substituted three times more often than other amino acids. Glycine can be substituted nine ways (Table 3), and the substitutions with each residue occurred as often as expected except for Ala which was underrepresented (4% compared with 13% expected). Ala is the least destabilising amino acid, and results in a milder clinical phenotype, which may have been overlooked clinically \((p<0.0001)[20]\).
Of the 113 non-Gly substitutions, the most common replacements were of Arg, Asp, Glu, Ser (26, 9.5%), Val (10, 4%) or Ala (7, 2.6%), to Gly.

Only 135 of the 432 Gly in the collagenous sequence were substituted (31%). This was comparable with COL1A1 where fewer than 10% of all variants were calculated to be known (Marini, 2007). Most substitutions were with one amino acid only.

Missense variants were not distributed evenly throughout the COL4A5 gene when exon size was taken into account (Fig 1). There were fewer mutations in exons 47 and 48, which suggested a milder phenotype or an ascertainment bias. It was unlikely that the fewer mutations were due to an embryonic lethal phenotype because the collagen IV α3α4α5 network is mainly expressed after infancy. However exons 47 and 48 correspond to the collagen IV α5 chain before the carboxy terminus, where there is a ‘gap’ for entry of the cleavage enzymes, and the major epithelial binding site on the parallel IV alpha3 chain [21]. Mutations were also underrepresented in exons 42 and 43 probably because these exons are small and not routinely sequenced.

CpG site mutations. There were 70 CpG sites among the 5076 nucleotide positions in COL4A5. Of all the mutations causing Alport syndrome, 89 were present at CpG sites which was more often than by chance (p less than 10^{-4} by Fisher’s exact test). Nonsense mutations were also observed more often at CpG sites. Of the 89 mutations at 70 CpG sites, 27 were non-sense changes at 5 sites (p less than 0.001 by Fisher’s exact test).

Gly substitutions within the collagenous domains were also overrepresented in COL4A5 mutations. Of the 491 missense mutations affecting the 1347 amino acid positions in collagen IV α5 chain, 435 (89%) were substitutions of one of the 449 collagenous domain Gly residues (p<0.001). Similarly, at the CpG sites, 46 missense mutations were observed at 43 CpG sites within the collagenous domains, with 39 resulting in Gly substitutions at 12 Gly positions (p less than 10^{-7} by Fisher’s exact test).

Splice site mutations. There were 273 splicing variants (23% of total number) with a variant within 10 nucleotides of the intron-exon boundary that was possibly pathogenic. At least one variant was identified for each intron, and there were 152 + (at the 3’ end of the exon) and 121 – (at the 5’ end of the exon) splice variants.

Founder mutations. Two hundred and sixty-five pathogenic variants (23%) were recorded more than once, but only 12 reported at least five times in apparently unrelated families (Table 4). Three were biochemically ‘severe’ mutations being a duplication or nonsense variant. A further three were Gly substitutions. Six resulted in renal failure at less than 30 years of age, and five in a milder phenotype with later onset renal failure.

Table 3. Observed versus expected likelihood of Glycine substitutions in the COL4A5, COL4A3 and COL4A4 genes in Alport syndrome and Thin basement membrane nephropathy. Observed number from the LOVD databases; expected number derived from data for collagen I [20].

Of the 113 non-Gly substitutions, the most common replacements were of Arg, Asp, Glu, Ser (26, 9.5%), Val (10, 4%) or Ala (7, 2.6%), to Gly.

Only 135 of the 432 Gly in the collagenous sequence were substituted (31%). This was comparable with COL1A1 where fewer than 10% of all variants were calculated to be known (Marini, 2007). Most substitutions were with one amino acid only.

Missense variants were not distributed evenly throughout the COL4A5 gene when exon size was taken into account (Fig 1). There were fewer mutations in exons 47 and 48, which suggested a milder phenotype or an ascertainment bias. It was unlikely that the fewer mutations were due to an embryonic lethal phenotype because the collagen IV α3α4α5 network is mainly expressed after infancy. However exons 47 and 48 correspond to the collagen IV α5 chain before the carboxy terminus, where there is a ‘gap’ for entry of the cleavage enzymes, and the major epithelial binding site on the parallel IV alpha3 chain [21]. Mutations were also underrepresented in exons 42 and 43 probably because these exons are small and not routinely sequenced.

CpG site mutations. There were 70 CpG sites among the 5076 nucleotide positions in COL4A5. Of all the mutations causing Alport syndrome, 89 were present at CpG sites which was more often than by chance (p less than 10^{-4} by Fisher’s exact test). Nonsense mutations were also observed more often at CpG sites. Of the 89 mutations at 70 CpG sites, 27 were non-sense changes at 5 sites (p less than 0.001 by Fisher’s exact test).

Gly substitutions within the collagenous domains were also overrepresented in COL4A5 mutations. Of the 491 missense mutations affecting the 1347 amino acid positions in collagen IV α5 chain, 435 (89%) were substitutions of one of the 449 collagenous domain Gly residues (p<0.001). Similarly, at the CpG sites, 46 missense mutations were observed at 43 CpG sites within the collagenous domains, with 39 resulting in Gly substitutions at 12 Gly positions (p less than 10^{-7} by Fisher’s exact test).

Splice site mutations. There were 273 splicing variants (23% of total number) with a variant within 10 nucleotides of the intron-exon boundary that was possibly pathogenic. At least one variant was identified for each intron, and there were 152 + (at the 3’ end of the exon) and 121 – (at the 5’ end of the exon) splice variants.

Founder mutations. Two hundred and sixty-five pathogenic variants (23%) were recorded more than once, but only 12 reported at least five times in apparently unrelated families (Table 4). Three were biochemically ‘severe’ mutations being a duplication or nonsense variant. A further three were Gly substitutions. Six resulted in renal failure at less than 30 years of age, and five in a milder phenotype with later onset renal failure.
Some of these mutations will have arisen from independent events and others from a single individual, but the distinction can only be made with haplotype analysis. These mutations allow us to examine the consistency of age of onset of renal failure and the effect of modifying genes. More founder mutations are likely but laboratories may not have not reported them because of their 'lack of novelty'.

**Genotype-phenotype correlation.** Clinical data were most complete for age at end-stage renal failure. Formal hearing and ophthalmic examinations were rarely reported to the testing laboratory.

Reported mutations were associated more often with a severe phenotype. The age at onset of renal failure was available for 237 COL4A5 mutations (12%) and the mean age was 24.3 years (Table 5). More mutations (162, 68%) were associated with end-stage renal failure before the age of 30 years, than later (75, 32%).

A severe mutation (rearrangement, large deletion, insertion/deletion, or nonsense change) was associated with a younger average age at onset of renal failure of 22.5 ± 7.0 years (n = 131) than in those without a severe mutation (26.7 ± 8.1 years, n = 106, p less than 0.01).

A direct nonsense mutation, that is where a codon was replaced by a stop signal, was associated with a younger average age at onset of renal failure of 21.4 ± 6.4 years than with other mutations types (p = 0.03).
There was no difference in the age at onset of renal failure in individuals with Gly substitutions with Arg, Glu or Asp compared with other amino acids, nor with non-Gly substitutions (p all greater than 0.05).

COL4A5 mutations were reported in 68 females. Nine of the 23 (39%) who developed renal failure had a direct or indirect nonsense mutation or rearrangement or insertion/deletion, in contrast to 9 of the 45 without renal failure (20%, p = 0.14).

DNA variants in COL4A3 and COL4A4

Many fewer DNA variants have been described for the COL4A3 and COL4A4 genes, presumably because autosomal recessive Alport syndrome is less common, and genetic testing is performed infrequently for Thin basement membrane nephropathy.

DNA variants in COL4A3 and COL4A4

Many fewer DNA variants have been described for the COL4A3 and COL4A4 genes, presumably because autosomal recessive Alport syndrome is less common, and genetic testing is performed infrequently for Thin basement membrane nephropathy.
Large deletions/indels/rearrangements. The proportions of duplications, insertions, short deletions and other indels were similar to those found in COL4A5.

Missense. Glycine substitutions were relatively less abundant than for COL4A5 (Table 2). This was unexpected since they are the most common change in X-linked Alport syndrome and other collagen diseases such as osteogenesis imperfecta [20]. The explanation may be that milder disease with heterozygous Gly substitutions was overlooked. Gly to Ala or Ser substitutions were again underrepresented for the COL4A3 and COL4A4 genes.

Too few missense variants were found to determine any mutational hot spots. Non-Gly substitutions were more common than in COL4A5, but their pathogenic significance was often not clear.

Nonsense. The % of direct nonsense mutations was similar to COL4A5 but the total % (of direct and potential indirect nonsense mutations) was fewer because fewer large insertions/deletions were reported.

Splicing. Very few potential splicing mutations were identified within the first 10 nucleotides of the intron-exon boundaries.

Founder mutations. Founder mutations were reported in both COL4A3 and COL4A4 in autosomal recessive Alport syndrome and Thin basement membrane nephropathy (Table 5). For example, the S969X variant in COL4A4 was the commonest variant in British populations, and other variants were reported from Cyprus.

Genotype-phenotype correlations. Clinical features were compared between individuals with autosomal recessive Alport syndrome caused by COL4A3 or COL4A4 pathogenic mutations and those with X-linked Alport syndrome and COL4A5 mutations. The age at onset of renal failure was known for some homozygous or compound heterozygous COL4A3 (n = 35) and COL4A4 (n = 25) pathogenic mutations where both variants were known. Overall the mean age at onset of end-stage renal failure was not different for individuals with COL4A3 (23.2 ± 9.3, years, 95% CI 20.1 to 26.5) or COL4A4 mutations (mean 25.4 ± 10.3 years, 95% CI 21.3 to 29.6) compared with COL4A5 mutations (24.4 ± 7.8 years, 95% CI 23.4 to 25.4, n = 237) (Table 4).

‘Severe’ mutations were large rearrangements, deletions, insertions or other changes resulting in a nonsense codon.

doi:10.1371/journal.pone.0161802.t005

Alport Syndrome: Further genotype-phenotype correlations
The age at onset of renal failure was also the same for homozygous and for compound heterozygous \textit{COL4A3} and \textit{COL4A4} mutations (21.5 ± 7.2, 95% CI 17.2–25.9, $n = 13$; and 21.8 ± 7.0, 95% CI 19.8 to 23.7, $n = 52$).

Subjects with two severe mutations (direct or indirect nonsense mutations, insertions/deletions) developed end-stage renal failure at a younger age than those with none (Table 4). Individuals with at least one direct nonsense \textit{COL4A3} or \textit{COL4A4} mutation also developed renal failure at a younger age than those with none. Thus, the age at onset of renal failure in autosomal recessive Alport syndrome depended on mutation severity using the same criteria as for \textit{COL4A5} mutations \cite{11,12}. However this study did not demonstrate any difference in the age at end-stage renal failure due to Gly substitutions with Arg, Glu or Asp compared with other substitutions for \textit{COL4A3} and \textit{COL4A4}.

Twenty \textit{COL4A3} or \textit{COL4A4} mutations were identified in the LOVD databases in individuals diagnosed clinically with autosomal dominant Alport syndrome. Seven only had developed end-stage renal failure, at a mean age of 42 ± 15.1 years (range 20–60). The others either did not have renal failure or the age at onset was not known.

**Biallelic and digenic mutations**

There are occasional reports of individuals with two \textit{COL4A5} mutations \cite{22,23}, and others with autosomal recessive Alport syndrome and mutations in both \textit{COL4A3} and \textit{COL4A4} with a later age at onset of renal failure \cite{15,24,25}.

**Discussion**

This study confirmed that \textit{COL4A5}, and \textit{COL4A3} and \textit{COL4A4} mutations in Alport syndrome all resulted in end-stage renal failure at the same age. Other studies have found that \textit{COL4A5} deletions, insertions, and nonsense variants, are associated with early onset renal failure \cite{11,12,13}. This study confirmed that two \textit{COL4A3} or \textit{COL4A4} mutations resulted in earlier onset renal failure than one or no severe mutations. Nonsense \textit{COL4A3} and \textit{COL4A4} mutations were also associated with a younger age at renal failure. Cohort studies indicate that hearing loss is common with all mutation types, and that the same mutation types that cause early onset renal failure in X-linked disease are associated with lenticulon and retinopathy \cite{14}.

The number of different published \textit{COL4A5} variants has increased from 176 in 1997 \cite{26}, to 520 by 2010 \cite{27}, and 1200 in 2015. Many more pathogenic variants have been reported for \textit{COL4A5} than for \textit{COL4A3} and \textit{COL4A4}. There was some bias in the types of mutations reported here (deletions and insertions were more common for \textit{COL4A5}) probably because of the detection techniques.

The major challenge for the future is to encourage all diagnostic laboratories including those that are commercially-based, to submit their variants to a database, together with accurate pathogenicity assessments and as much clinical information as possible. The classification of some so-called benign variants will be revised. We will understand better genotype-phenotype correlations for heterozygous \textit{COL4A3} and \textit{COL4A4} mutations in Thin basement membrane nephropathy, and any genetic distinctions from variants that cause autosomal dominant Alport syndrome. In addition we will better understand the consequences of biallelic, triallelic and digenic \textit{COL4} mutations \cite{25}, and possibly why some heterozygous \textit{COL4} mutations are associated with proteinuria.

Increasingly the value of sharing variants and pathogenicity assessments is realised. Some countries allow all variants identified in public laboratories to be shared in public databases without specific assent, and IRBs internationally are finding that the public benefit of sharing
outweighs any small adverse risk. Our study exemplifies the advantages of sharing variants in a rare disease.

Acknowledgments

This work was presented in part at the Alport Mutation Updates at Oxford University, January 2014 and at the University of Gottingen, September 2015. We would like to thank the many patients who allowed us to use their data, and the physicians who referred them. We would also like to acknowledge mutations submitted by the ARUP laboratory, Salt Lake City, USA, and by the Hopital Necker-Enfants-malades, Paris, France.
