The differential diagnostics in Rett syndrome has evolved with the development of next generation sequencing based techniques and many patients have been diagnosed with other syndromes or variants in newly described genes where the associated phenotype(s) is yet to be fully explored. The term Rett-like refers to phenotypes with distinct overlapping features of Rett syndrome where the clinical criteria are not completely fulfilled. In this paper we have combined a review of Rett-like disorders with data from a Danish cohort of 35 patients with Rett-like phenotypes emphasizing the diagnostic overlap with Pitt-Hopkins syndrome, Cornelia de Lange syndrome with SMC1A variants, and epileptic encephalopathies for example due to STXBPI variants. We also found a patient with a pathogenic variant in KCNB1, which has not previously been linked to a Rett-like phenotype. This study underlines the clinical and genetic heterogeneity of a Rett syndrome spectrum, and provides an overview of the Rett syndrome-related genes described to date, and hence serves as a guide for diagnosing patients with Rett-like phenotypes.
The neurodevelopmental disorder Rett syndrome (RTT) was first described in 1966 by Dr. Andreas Rett, who reported 22 girls with loss of speech and hand use, and who developed hand stereotypies\(^1\). Apart from the classical/typical form (RTT) there are atypical forms of RTT (atypical RTT) with different clinical subgroups such as “preserved speech variant”\(^2\), the “early seizure variant”\(^3,4\) and the “congenital variant”\(^5\). Today, the term Rett-like is used when there is an overlapping phenotype with typical or atypical RTT, but in whom the clinical criteria are not fulfilled. There are to date no formal published consensus criteria for a Rett-like diagnosis, and thus this description can be given to any patient with different combinations of the distinct features of RTT.

The genetic causes of typical RTT, atypical RTT and Rett-like disorders have been intensely studied. Typical RTT patients almost exclusively have pathogenic \textit{MECP2} variants\(^6\), while atypical RTT and Rett-like patients show genetic heterogeneity. The most common genes involved apart from \textit{MECP2} are: \textit{CDKL5}, in which variants cause the early onset seizure disorder\(^7\) and \textit{FOXG1}, which is responsible for the congenital RTT variant\(^8\). Several additional new genes have been suggested to be associated with atypical RTT and a Rett-like disorder\(^9\)\textsuperscript{-12}. These studies have also revealed previously unrecognized clinical similarities of Rett spectrum phenotypes with other neurodevelopmental disorders. One of the unexpected findings has been the identification of \textit{SMC1A} variants, which are traditionally linked to Cornelia de Lange syndrome, in Rett-like patients\(^13\). Furthermore, several Rett-like patients have pathogenic variants in epileptic encephalopathy genes\(^14\). From a clinical perspective these findings enable an improved comprehension of the genetic landscape of atypical RTT and Rett-like disorders, potentially transforming the primary clinical diagnosis to a genetic one. From a research perspective, the genetic landscape is yet to completely unfold, and some of the genes associated with these phenotypes may be linked through similar functional pathways.

In this study, we present a genetic review of a Rett-like spectrum (typical RTT, atypical RTT, Rett-like disorder) and our findings in a Danish Rett-like cohort, including association of the epilepsy gene, \textit{KCNB1}, as a new Rett-like gene. The purpose of this review is to provide a guide for molecular diagnosis of patients with Rett-like phenotypes.

**RETT SYNDROME**

RTT is mainly seen in females and presents with only a few neurodevelopmental symptoms before the age of 6-18 months\(^15\). A period of regression will then occur, and abilities especially related to
hand function and speech can deteriorate or be lost altogether\textsuperscript{16}. Hand stereotypies are a main feature and the patients often have severely impaired functional use of their hands\textsuperscript{17}. Another distinct clinical feature often present which can help point to the diagnosis is the breathing abnormalities (including hyperventilation and/or breath holding episodes)\textsuperscript{18}. Patients all have intellectual disability (ID). Other features that often develop over time include progressive microcephaly\textsuperscript{19}, and epilepsy (occurring in approximately 68\% at a mean age of 4.7 years)\textsuperscript{20, 21}. Scoliosis is also very common\textsuperscript{16}. Facial dysmorphism is not distinct, but few have subtle dysmorphic facial features which do not enable a clinical diagnosis\textsuperscript{22}.

Today the international diagnostic criteria published in 2010\textsuperscript{23} are used to assist in establishing the clinical diagnosis of RTT (listed in Table 1). RTT patients should have four main criteria (partial or complete loss of purposeful hand movements, partial or complete loss of spoken language, a gait abnormality, and stereotypic hand movements); while a diagnosis of atypical RTT is suggested if the patient has two or more of the main in addition to five or more of the supportive criteria\textsuperscript{23}. Both forms are characterized by a period of developmental regression followed by recovery or stabilization. In addition, the presence of any of the following features exclude a diagnosis of typical or classic RTT: a brain injury, a neurometabolic disease or neurological infection, and abnormal psychomotor development with an onset before the age of 6 months \textsuperscript{23}.

\textit{"Insert table 1 about here"}

THE RETT SYNDROME GENES

\textit{MECP2}, encoding methyl CpG binding protein 2, is the major gene related to RTT and there are over 4600 \textit{MECP2} variants (pathogenic, benign, or with unknown significance) described in the literature\textsuperscript{24}. \textit{MECP2} variants mainly cause RTT (including classical/typical and variant/atypical RTT), but may rarely also be associated with non-syndromic neurodevelopmental disorders including autism\textsuperscript{25}.

Variants in \textit{CDKL5} (Cyclin-dependent kinase-like 5) have been reported in about 500 patients\textsuperscript{24} and the most notable clinical feature of patients with pathogenic mutations of this gene is early onset epilepsy. These patients have ID and progressive microcephaly\textsuperscript{26}. Stereotypic hand movements, respiratory impairment with breath holding and hyperventilation, and severely impaired speech, hand function and gait may also be observed \textsuperscript{27, 28}. These features are suggestive of RTT, but normal development during the first 6 months is rare in these patients and they often have
facial dysmorphic features\textsuperscript{29, 30}. Traditionally, the term Hanefeld or early onset epilepsy variant of RTT\textsuperscript{4, 26} has been used for this diagnosis, but recently the term CDKL5 disorder has been introduced and is considered a separate clinical disorder from RTT\textsuperscript{31}.

\textit{FOXG1} variants are less common (approximately 80 cases in total\textsuperscript{29}) and neurodevelopmental impairment is already observable in early infancy. As \textit{FOXG1} is located on chromosome 14, variants affect males as well as females. This condition has therefore been called the congenital variant of RTT\textsuperscript{8}, and recently the term \textit{FOXG1} syndrome has been introduced\textsuperscript{29}. These patients exhibit profound motor dysfunction, and stereotypic hand movements and abnormal breathing can be present\textsuperscript{32}. There is rarely any speech development and eye contact is poor\textsuperscript{32, 33}. Epilepsy is common although the age of onset can vary substantially\textsuperscript{34}. They have progressive microcephaly\textsuperscript{33, 35} and MRI of the brain reveals poor myelinization and/or corpus callosum hypoplasia or agenesis\textsuperscript{32}.

\section*{MANY GENES, MANY DISORDERS}

Apart from these three genes, there are at least 28 OMIM morbid genes (https://www.omim.org/) described in literature in which variants may cause gene disorders/syndromes with overlapping Rett-like phenotypes (Table 2)\textsuperscript{9, 10, 14, 36-38}. Some of these genes are associated with well-known syndromes such as Pitt-Hopkins syndrome (\textit{TCF4, CNTNAP2, NRXN1}), Cornelia de Lange syndrome (\textit{SMC1A}), Phelan-McDermid syndrome (\textit{SHANK3}), Kleefstra syndrome (\textit{EHMT1}), Christianson type X-linked mental retardation syndrome (\textit{SLC9A6}), Angelman syndrome (\textit{UBE3A}), and Glass syndrome (\textit{SATB2}). In addition, a substantial number of genes are epileptic encephalopathy genes (\textit{STXBP1, SCN1A, SCN2A, SCN8A, GRIN2A, GRIN2B, HCN1, SLC6A1, KCNA2, EEF1A2} and \textit{KCNB1}).

\section*{DANISH COHORT OF RTT, ATYPICAL RTT AND RETT-LIKE PHENOTYPES}

In Denmark, patients with clinical features suggestive of RTT are referred to the National Danish Centre for Rett syndrome and currently, we have registered 146 living patients. All these patients were initially investigated for the three known RTT genes and the sequence variant distribution is: \textit{MECP2} – 99 cases, \textit{CDKL5} – 10 cases, and \textit{FOXG1} – 2 cases.
Among the patients, without deficiencies in one of these three genes (n=35), pathogenic sequence variants were identified in *SCN2A* (n=1), *STXBP1* (n=2) and *TCF4* (n=1); all genes previously linked to Rett-like phenotype (Table 2), using different technologies including single gene or whole exome sequencing, and a previously described epilepsy gene panel\(^3^9\). Notably, in one patient we identified a *de novo* variant in *KCNB1*, which was not previously linked to Rett syndrome spectrum. Patient 2 (*STXBP1*) and patient 3 (*SCN2A*) have previously been published\(^4^0, 4^1\) (Table 1).

Remaining patients were investigated using an in-house gene panel which included the genes described in Table 2. Through this approach we identified two patients with variants within *SMC1A* (n=1) and *SHANK3* (n=1) (Table 1). With these results pathogenic variants of a total of 23 different have been found in RTT/atypical RTT/Rett-like patients (Fig. 1).

The project was approved by the Danish regional ethics committee, the regional dataprotection agency and informed consent was obtained from all participating patients.

"Insert Fig. 1 about here"

**CLINICAL OR GENETIC DIAGNOSIS?**

The description of variants within several different genes in patients with overlapping phenotypes creates practical challenges with diagnosis in clinical practice. Next generation sequencing based methodologies (gene panels or whole exome/genome sequencing) have overcome some difficulties and diagnosis tends to move from a sole clinical to a genetic confirmation. However, understanding the clinical picture of different disorders is crucial for selection of the most relevant genes to be investigated and for assessing the clinical significance of genomic variants identified in these genes. In the following section we will compare different disorders and causative genes in comparison with RTT features (Table 2).

**Pitt-Hopkins and Pitt-Hopkins like syndromes**

Pitt-Hopkins syndrome was first described in 1978 in patients with distinct facial dysmorphism and overbreathing\(^4^2\). Neurodevelopment and speech are severely impaired, and several patients have progressive microcephaly and seizures\(^2^8, 4^3\). Gait is often ataxic. Fetal pads on fingers and toes, and stereotypic hand movements such as hand clapping are important features. *TCF4* is the main...
causative gene for the classical Pitt-Hopkins phenotype; variants in this gene have also been reported in two patients with a Rett-like phenotype. In the Danish cohort a single patient suspected of having RTT due to hyperventilation and hand stereotypies has a pathogenic TCF4 variant (Table 1).

Bi-allelic loss-of-function variants in CNTNAP2 or NRXN1 can also result in a Pitt-Hopkins like phenotype. These patients also have severe ID and in some regression or stagnation in development. Other prominent symptoms include epileptic seizures, a speech deficit with loss of verbal skills, and hyperventilation; and some of the patients are described as being non-dysmorphic. Even though variants of these genes are not yet found in Rett-like patients, they should be included in the genomic analyses of this patient group due the phenotypic overlap.

Cornelia de Lange syndrome (CdLS)

CdLS is characterized by ID, a recognizable pattern of dysmorphic facial features (synophrys, thick arched eyebrows, long eye lashes and downslanting palpebral fissures), hirsuitism, short neck, and possible presence of major malformations, such as limb defects. There are five known genes associated with CdLS. Mutations in SMC1A are the second most common cause of CdLS, and commonly associated with seizures, but limb defects are rare. The phenotype associated with SMC1A variants may in some include Rett-like features (Fig. 2). They may have hand stereotypies, apnea, microcephaly, and some have a period of regression. SMC1A variants have been described in several patients with a Rett-like disorder, and we identified a single patient with atypical RTT in the Danish cohort (Fig. 1). The phenotypic spectrum of SMC1A spans from CdLS to Rett-like phenotypes, and SMC1A can now be considered as the fourth most common gene mutated in patients with a clinical Rett syndrome spectrum (Fig. 1).

Phelan-McDermid syndrome and SHANK3

Phelan-McDermid syndrome patients have various degrees of ID and speech deficits, epilepsy, hypotonia, structural brain and/or renal abnormalities and prevalent dysmorphic features, including a pointed chin and dysplastic toenails. The syndrome is caused by microdeletions encompassing SHANK3 at 22q13 or a pathogenic variant in this gene, which is also associated with
autism\textsuperscript{52}. \textit{SHANK3} variants have been reported in two patients with RTT \textsuperscript{53} and a Rett-like phenotype\textsuperscript{12}, respectively. In the Danish cohort a \textit{SHANK3} variant was identified in a single patient, who fulfills some of the main criteria of RTT, but due to her normal gait, not categorized as typical RTT. On the other hand she has classical autistic behavior compatible with a \textit{SHANK3} variant\textsuperscript{52}.

**Christianson type X-linked mental retardation**

Christianson type X-linked mental retardation syndrome was first described in 1999 in a large family with males affected with profound ID, absence of speech and epilepsy \textsuperscript{54}. Since then, several patients with common features (such as ataxic gait, hyperkinetic movements, a happy demeanor and poor fine motor skills) have been reported\textsuperscript{55, 56}. Epilepsy is reported in approximately 80\% of cases, and some have had a period of regression\textsuperscript{55, 56}. Because of this combination of clinical features, the syndrome has been considered a differential diagnosis of Angelman syndrome\textsuperscript{57}. Christianson type X-linked mental retardation is caused by pathogenic variants in \textit{SLC9A6} and has also been identified in two Rett-like patients\textsuperscript{11, 12}.

**\textit{SATB2} Associated syndrome (Glass syndrome)**

Pathogenic variants in \textit{SATB2} have been identified in patients with neurodevelopmental disability, speech deficits and nonspecific dysmorphic features, which together have been named as Glass syndrome or “\textit{SATB2} associated syndrome”. Many patients have cleft palate or dental anomalies, but seizures were not prominent and they do not exhibit neurodevelopmental regression\textsuperscript{58, 59}. \textit{SATB2} variants have also been described in two patients with a Rett-like phenotype, both of whom had hand stereotypies, impaired hand function and ID, but had no period of regression or seizures\textsuperscript{37}. \textit{SATB2} associated syndrome should be considered when evaluating Rett-like patients, especially if they have oral anomalies.

**Kleefstra syndrome**

The key features of Kleefstra syndrome are ID, hypotonia, dysmorphic features and cardiac defects\textsuperscript{36, 60}. However, some characteristic symptoms overlapping with RTT, such as speech loss and impaired walking, may be present\textsuperscript{61}. Additional nonspecific RTT features, including microcephaly, a sleep disorder and teeth grinding, have been described numerous\textsuperscript{60}. Some patients have stereotypic movements and respiratory abnormalities, but are different to those observed in
RTT patients\textsuperscript{36, 61}. Kleefstra syndrome is caused by 9q34.3 microdeletions including \textit{EHMT1} or sequence variants of this gene\textsuperscript{60}. \textit{EHMT1} variants have not yet been reported in patients with a Rett-like phenotype, but have great phenotypic overlap and has been linked to the Rett-like spectrum\textsuperscript{36}.

**Angelman syndrome (AS)**

AS and RTT have often been described as potential differential diagnoses of each other, because they both present with severe ID, microcephaly, speech deficits and abnormal hand movements\textsuperscript{36}. However, there are clinically identifiable differences between AS and RTT: AS patients have facial dysmorphism and they do not have hand wringing, but hand flapping. The EEG is almost always abnormal and often with a classical AS pattern\textsuperscript{35}. AS can be caused by several genetic/epigenetic mechanisms, including variations in \textit{UBE3A}\textsuperscript{62}, variants of which have not yet been reported in Rett syndrome patients.

**Epilepsy**

More than 500 genes have been associated with epilepsy, including genes causing encephalopathy, and pathogenic variants of several of the latter have also been described in patients with Rett-like features (Table 2, Fig. 1). In Fig. 3 we have compiled the age of onset of seizures for all the genes that have been associated with RTT or Rett-like clinical spectrum, as the type and age of onset of epilepsy can be an important indicator of which group of genes is likely to be causative. The epileptic encephalopathies may overlap with Rett-like phenotypes, especially where there is a period of regression with the onset of epilepsy, together with progressive microcephaly, and intellectual, speech and motor deficits\textsuperscript{14}. Epileptic encephalopathies are defined as conditions where the progressive disturbance in cerebral function is thought to be the result of the epileptiform abnormalities\textsuperscript{63}. However, in some of the so-called epileptic encephalopathies it is likely that the neurodevelopmental co-morbidities are primary, since neurodevelopmental abnormalities can occur before the onset of seizures, and in fact some patients never experience any seizures. This has been the case with \textit{STXBP1} variants, for instance, where patients have moderate to severe ID, speech deficits, ataxia and tremor\textsuperscript{64-66}; epilepsy is described in 95\% of cases with a median age of 6 weeks but ranging from 1 day to 12 years\textsuperscript{65}. Six patients with a Rett-like phenotype, including two Danish patients, have been found to have \textit{STXBP1} variants\textsuperscript{10, 11, 14, 67} (Fig. 1).

Variants in \textit{SCN1A}, \textit{SCN2A} and \textit{SCN8A} lead to early onset of seizures and variants in these genes have been described in single cases with Rett-like features. The development of epilepsy is
variable in these cases, but in all of them a period of regression has followed the epileptic seizures\textsuperscript{12, 14, 68}. In addition, patients may have ataxia, encephalopathy, various degrees of ID and hand stereotypies, and so these genes should be considered in Rett-like patients with early onset epilepsy. The severity of epilepsy is variable in patients with \textit{SCN1A}, and an \textit{SCN1A} variant was found in one patient with a Rett-like phenotype\textsuperscript{12}. In the Danish cohort we identified a single patient with an \textit{SCN2A} variant. She was referred with the suspicion of RTT, but her clinical history was more suggestive of a primary epileptic encephalopathy disorder, since the regression was related to the onset of intractable epilepsy.

\textit{GRIN2A} and \textit{GRIN2B} are two genes which cause ID and childhood onset epilepsy\textsuperscript{69}. Variants in \textit{GRIN2A} cause a clinical heterogeneous disorder, and have been reported in 20\% of patients with Landau-Kleffner syndrome, continuous spike and waves during slow-wave sleep syndrome and electroclinically atypical rolandic epilepsy\textsuperscript{70}. \textit{GRIN2B} is currently considered an epileptic encephalopathy gene\textsuperscript{71, 72}, but variants have been reported in patients both with and without epilepsy. Evaluation of larger cohorts is needed to better define the phenotype associated with variants in this gene. Notably, variations in \textit{GRIN2A} and \textit{GRIN2B} have been reported in three Rett-like patients, all of whom had hand stereotypies, whereas the patient with a \textit{GRIN2B} variant also had a breathing disturbance\textsuperscript{11, 12}.

Variants of \textit{HCN1} and \textit{SLC6A1} have been reported only in few patients in epileptic encephalopathy cohorts\textsuperscript{73, 74}; and \textit{EEF1A2} variants were detected in a few patients with ID, dysmorphic facial features epilepsy with a variable age of onset\textsuperscript{75}. Variants in these genes are described in single patients with a Rett-like phenotype, including stereotypic hand movements and breathing abnormalities as distinct features of RTT\textsuperscript{11, 12}.

\textit{KCNA2} variants are phenotypically linked to infantile epilepsy and episodic ataxia\textsuperscript{9} but also to hereditary spastic paraplegia\textsuperscript{76}. The only Rett-like phenotype patient with a \textit{KCNA2} variant had an onset of regression a few months before the onset of intractable epilepsy. She also had loss of hand skills, hand stereotypies, microcephaly and a speech deficit\textsuperscript{9}.

\textit{KCNB1} has previously been described as a gene related to epileptic encephalopathy and ID, and sequence variants have only been described in a few patients, one of whom had handwringing\textsuperscript{77, 78}. \textit{KCNB1} variants have not previously been described in Rett-like patients, even though they may be associated with clinical features overlapping with those of RTT. In the Danish cohort we identified a single case with pathogenic \textit{KCNB1} variant. The patient displayed many RTT features, including neurodevelopmental regression, loss of hand function, hand stereotypies and a speech deficit, and
the onset of cognitive and motor decline was prior to her seizures. We suggest that this finding warrants the inclusion of *KCBN1* in the expanding group of Rett-like genes.

“Insert Fig. 3 about here”

**WDR45 and other genes**

*WDR45* variants were first linked to a neurodegenerative disorder with iron deposits, and have been reported in four patients with an initial diagnosis of RTT or a Rett-like disorder, mainly because of cognitive and motor decline and hand stereotypies. Patients with *WDR45* variants can be interpreted as Rett-like in the early stages of development before the brain MRI scans displaying the iron deposits typical of WDR45 disorder become obvious. Variants of all the other genes listed in Fig. 1, except for *WDR45*, have been observed in only one or two patients, and these genes are described in more detail in the supplementary material.

“Insert link to supplementary material about here”

**CLINICAL SIGNATURES OF RETT-LIKE PHENOTYPES**

In a cohort of 35 Danish patients with Rett-like features but without *MECP2*, *CDKL5* or *FOXL1* variants, six patients revealed pathogenic changes in five other genes (*SMC1A*, *TCF4*, *SHANK3*, *STXBP1* and *SCN2A*), previously linked to a Rett-like phenotype. Furthermore, we identified a *KCNB1* variant, expanding the range of “Rett spectrum genes.”

These findings, together with the published reports, underscore that RTT and Rett-like phenotypes represent a clinically heterogeneous group of disorders, which may be designated as being part of a Rett syndrome spectrum (Fig. 1). The underlying genetic defects are also quite heterogeneous, with pathogenic variants reported in a number of genes, but where variants of each gene are detected in only a few patients, as outlined above. However, a number of recurrences have been reported in a number of genes such as *SMC1A*, *TCF4*, *SHANK3* and *WDR45*, as well as a group of epileptic encephalopathy genes, all of which should be considered in the molecular diagnosis of patients with Rett-like phenotypes.

Since the reports of Andreas Rett and Bengt Hagberg and international colleagues, who undertook thorough initial evaluations of patients with RTT, unique co-morbidities have been
identified. These co-morbidities distinguish patients with RTT from those who have other neurodevelopmental disorders. Some of the recent genes associated with Rett-like phenotypes were detected through a genotype first approach as a consequence of large scale genetic screening technologies, but not based on the clinical phenotype of the patients. However, it is possible to describe co-morbidities when patients are extensively phenotyped and compared to an adequate cohort of cases with mutations in the same gene. Descriptions of genes in a specific group of patients with a single major clinical feature like epilepsy may not emphasize other features or co-morbidities. Therefore, the full spectrum of the clinical picture will only be revealed when larger cohorts of patients with pathogenic variants of the same gene are described. This can lead to the “lumper” and “splitter” conundrum, where, for instance, newly identified genes associated with a Rett-like phenotype and severe epilepsy may be perceived as primary epileptic encephalopathies, or may be perhaps cast as separate syndromes based on their spectrum of co-morbidities. This has been discussed especially with regards to STXBP1 variants that have been recurrently reported in Rett-like patients (Fig. 1). We also suggest a new “Rett-like gene”, namely KCNB1, where several patients harbouring mutations in this gene have handwringing and regression.

In the Danish cohort we found that using the clinical criteria described by Neul et al (2010), the diagnosis of RTT is often very clear and pinpoints to a phenotype associated with MECP2 variants with great accuracy. However, it can be argued if the atypical RTT criteria really apply to patients with variants in CDKL5 and FOXG1, since these patients often have early neurodevelopmental symptoms and/or early onset epilepsy. We find that when diagnosing Rett-like patients it is helpful to establish the age of onset of epilepsy as a pointer to the correct molecular diagnosis (Fig. 3). In the Danish cohort, a female patient was molecularly diagnosed, at the age 52 years old, with a CDKL5 variant by direct sequencing, which was performed because clinical examination and a thorough medical history revealed a period of severe epilepsy in early infancy. Thus, it should always be remembered that the phenotype may evolve with time. However, one must be cautious about applying hard and definite rules. For instance for FOXG1 the mean age of onset of seizures has been reported as 6.8 years, but seizures can occur as early as 6 months of age, and not all of the patients have seizures (87%)34. Thus, a variant in this gene may be considered if there are other features suggestive of a FOXG1 defect, regardless age of onset of seizures (Fig. 3).

When evaluating a patient who does not fulfill the clinical RTT criteria but has overlapping features, some key features should be taken into consideration in order to establish the diagnosis: psychomotor development should be carefully assessed for the first year of life to evaluate the age
of onset of regression, and the age of onset of epilepsy. Furthermore, careful characterization of hand movements and breathing pattern are invaluable. Because of the clinical and genetic heterogeneity, the diagnostic approach for patients with a Rett-like phenotype is shifting to a genotype first approach using gene panels, whole exome or genome sequencing. Nevertheless the clinical evaluation with identification of distinct clinical features is still highly crucial to assess the validity of causation of the putative sequence variants. Furthermore, as more patients with variants in the same genes are identified, clinical subgroups can be outlined.

PERSPECTIVES
From a clinical perspective an overview of the genes involved in typical RTT, atypical RTT and Rett-like phenotypes enables a better understanding of the genetic landscape of the RTT spectrum. From a research perspective the genes associated with Rett-like phenotypes need to be elucidated further in order to gain a more complete understanding of the genetic and functional networks involved. Apart from the known genes, variants in a number of other genes with yet unknown functions have been found through screening of large Rett-like phenotype cohorts\textsuperscript{10,12}. Some of these may represent new candidate genes and further investigations of future cohorts and functional studies are necessary to establish their potential role in this disease pathogenesis. Furthermore, elucidation of the functional pathways involved could pave the way for the development of future targeted therapies.

Acknowledgements
We thank the patients and their families for participating in the project. The research has been funded by “Dr. Louise Børnehospitals Fond” and “Fonden til Lægevidenskabens Fremme”.

Diagnostic criteria for Rett syndrome:

Required diagnostic Criteria

Age for a period of regression followed by recovery or stabilization: 1 1/2 years none 17 months 6 months none 5 1/2 years old 2 1/2 years

Exclusion Criteria for typical RTT

| Brain injury | no | no | no | no | no | no | no |
| Neurometabolic disease, or severe infection | no | no | no | no | no | no | no |
| Grossly abnormal development first 6 months | no | yes | no | no | yes | no | no |

Main Criteria

| Hand skills | partial loss | impaired | poor | lost | poor | partial loss | partial loss |
| Language | lost | never acquired | never acquired | never acquired | never acquired | partial loss | lost |
| Gait | partial loss | impaired | Stereotypies or automatisms | hand wringing | hand wringing | hands to mouth | hand wringing |

Supportive Criteria for atypical RTT

| Breathing abnormality | yes | no | yes | yes | yes | no | yes |
| Bruxism | yes | yes | yes | no | no | yes | no |
| Impaired sleep pattern | yes | no | yes | yes | yes | yes | no |
| Abnormal muscle tone | yes | yes | yes | yes | yes | no | yes |
| Peripheral vasomotor disturbances | no | no | no | no | no | no | no |
| Scoliosis/kyphosis | yes | yes | no | no | no | no | yes |
| Growth retardation | yes | no | yes | no | no | no | yes |
| Small cold hands and feet | yes | no | yes | no | no | no | yes |
| Inappropriate laughing/screaming spells | no | no | yes | no | yes | yes | no |
| Diminished response to pain | yes | yes | yes | no | no | yes | no |
| Intense eye communication | no | yes | no | no | no | no | no |

RTT Diagnosis (based on the Neul criteria)

Atypical | Atypical | Atypical | Typical | RTT-like | RTT-like | Typical

</table>

Note: This table lists the genotypes and phenotypes associated with Rett-like diagnoses and differential diagnoses. The table is based on the 2020 classification of Rett syndrome. The table includes genes associated with Rett syndrome, as well as genes associated with other conditions such as Angelman syndrome, X-linked conditions, and TSC-like features. The table also includes information on structural brain changes associated with Rett syndrome.

Table 2. List of causative genes in Rett-like diagnoses or differential diagnoses and the phenotypical overlap with Rett syndrome.
Figure 1. 23 OMIM genes found in Rett-like phenotypes in literature (dark grey) and in the Danish database (light grey).
Figure 2. Clinical spectrum of SMC1A spanning from Rett syndrome to Cornelia de Lange Syndrome. The photographs belong to the same patient. On the left photograph her hand wringing can be seen, but the eyebrows are covered. On the right side the synophrys is slightly observable, but her hand movements cannot be seen as her hands are being held. In this respect she has the two very characteristic symptoms of both syndromes simultaneously.

Photography on the right courtesy of Sofie Amalie Kloughart.
Figure 3:
Average time for first epileptic seizure.* indicates that >5% of patients with variations in this gene have been reported without epilepsy.
