Model projections on the impact of HCV treatment in the prevention of HCV transmission among people who inject drugs in Europe

Graphical abstract

Highlights

- Chronic HCV prevalence and treatment rates among PWID vary widely across Europe.
- HCV treatment scale-up is required in most sites to reduce HCV transmission.
- Increasing OST/NSP coverage enhances HCV treatment prevention benefit.

Lay summary

Measuring the amount of HCV in the population of PWID is uncertain. To reduce HCV infection to minimal levels in Europe will require scale-up of both HCV treatment and other interventions that reduce injecting risk (especially OST and provision of sterile injecting equipment).

Background & Aims: Prevention of hepatitis C virus (HCV) transmission among people who inject drugs (PWID) is critical for eliminating HCV in Europe. We estimated the impact of current and scaled-up HCV treatment with and without scaling up opioid substitution therapy (OST) and needle and syringe programmes (NSPs) across Europe over the next 10 years. We parameterised an HCV transmission model to setting-specific data that project chronic HCV prevalence and incidence among PWID.

Methods: We collected data on PWID HCV treatment rates, PWID prevalence, HCV prevalence, OST, and NSP coverage from 11 European settings. We parameterised an HCV transmission model to setting-specific data that project chronic HCV prevalence and incidence among PWID.

Results: At baseline, chronic HCV prevalence varied from <25% (Slovenia/Czech Republic) to >55% (Finland/Sweden), and <2% (Amsterdam/Hamburg/Norway/Denmark/Sweden) to 5% (Slovenia/Czech Republic) of chronically infected PWID were treated annually. The current treatment rates using new direct-acting antivirals (DAAs) may achieve observable reductions in chronic prevalence (38–63%) in 10 years in Czech Republic, Slovenia, and Amsterdam. Doubling the HCV treatment rates will reduce prevalence in other sites (12–24%; Belgium/Denmark/Hamburg/Norway/Scotland), but is unlikely to reduce prevalence in Sweden and Finland. Scaling-up OST and NSP to 80% coverage with current treatment rates using DAAs could achieve observable reductions in HCV prevalence (18–79%) in all sites. Using DAAs, Slovenia and Amsterdam are projected to reduce incidence to 2 per 100 person years or less in 10 years. Moderate to substantial increases in the current treatment rates are required to achieve the same impact elsewhere, from 1.4 to 3 times (Czech Republic and France), 5–17 times (France, Scotland, Hamburg, Norway, Denmark, Belgium, and Sweden), to 200 times (Finland). Scaling-up OST and NSP coverage to 80% in all sites reduces treatment scale-up needed by 20–80%.

Conclusions: The scale-up of HCV treatment and other interventions is needed in most settings to minimise HCV transmission among PWID in Europe.

Lay summary: Measuring the amount of HCV in the population of PWID is uncertain. To reduce HCV infection to minimal levels in Europe will require scale-up of both HCV treatment and other interventions that reduce injecting risk (especially OST and provision of sterile injecting equipment).

Introduction

Chronic hepatitis C virus (HCV) infection is a leading cause of liver disease and morbidity, causing more deaths than HIV in the United States and other high-income countries.1–4 Preventing HCV transmission among people who inject drugs (PWID) is critical for averting future liver disease in Europe and elsewhere5 and new HCV infections in this group.6 Primary prevention through opioid substitution therapy (OST) and high-coverage needle
and syringe programmes (NSPs) can reduce HCV transmission among PWID and averts new HCV infections, but substantial reductions in HCV prevalence are unlikely to be achieved without scaling-up HCV treatment. The arrival of highly effective and short-duration direct-acting antivirals (DAAs) with cure rates (sustained viral response [SVR]) above 90% for all genotypes has made HCV “treatment as prevention” more than a theoretical possibility. However, the current high cost of DAA regimes (often $>30,000 per treatment regime in higher-income countries) is a barrier to scaling-up treatment in most countries. European guidelines previously recommended prioritising DAAs for patients with advanced liver disease. Now, they suggest that HCV treatment should also be provided to people with a risk of transmitting HCV, such as PWID. A recent economic model suggested that, in general, it is more cost effective to delay treatment of a mild disease until more moderate stages of fibrosis. However, when these individuals have an ongoing transmission risk, they should be prioritised for early treatment over other patient groups.

In this paper, we estimate the current HCV treatment rates and coverage of OST and NSP in PWID across 11 sites in Europe. We assess the impact of these and scaled-up HCV treatment rates and other primary prevention on HCV prevalence and incidence over the next 10 years.

Materials and methods

Model

We used a dynamic deterministic mathematical model of HCV transmission among PWID, stratifying PWID according to intervention status (no OST or NSP, on OST, on NSP, or both) alongside HCV infection and treatment status (susceptible and never infected, previously infected, chronically infected, on treatment, and treatment failure). In three sites (Czech Republic, Finland, and Sweden), PWID are also stratified by drug type (opioid or methamphetamine/amphetamine). PWID enter the model through a constant rate that individuals initiate injecting. All PWID are assumed initially susceptible to HCV infection. Susceptible PWID can become infected at a per capita rate proportional to the background prevalence of the disease, which changes as HCV treatment increases. Transmission is reduced by a fixed multiplicative cofactor dependent on OST and NSP status. Once infected, PWID either transition to the chronically infected group (Ab+, RNA+), or spontaneously clear infection and transition to the previously infected group (Ab+, RNA-). This previously infected group is assumed to be reinfected and clear infection at the same rate as susceptible PWID. Chronically infected PWID (both primary and reinfection) can be treated. If treatment is successful and SVR is attained, PWID transition to the previously infected group. However, if SVR is not attained, PWID transition to the treatment-failure group. In the baseline model, treatment failures cannot be retreated. Once treatment is switched to DAAs, we assume that treatment failures can be retreated. PWID leave the model through permanent cessation of injecting, or drug-related or non-drug-related mortality. All PWID enter the model with no coverage of OST or NSP, and transition between the different intervention states (OST and/or NSP) at site-specific fixed per capita rates. Further details of the model, including model equations, are in the Supplementary materials.

Model parameterisation and calibration

The model was parameterised to each of the 11 sites (see Table 1 and Tables S1a–S1l for site-specific information). For sites with opioid injecting only, 2,500 model parameter sets were randomly sampled from the parameter uncertainty distributions (see Supplementary materials). For each parameter set, the model was fit to the PWID population size by varying the rate that individuals initiate injecting, to OST and NSP coverage levels by varying the recruitment rates onto OST and NSP, and to either the chronic or antibody HCV prevalence at a site-specific time point by varying the transmission rate. For Czech Republic, Finland, and Sweden, the model was fit to more parameters (see Supplementary materials for further details). HCV incidence was estimated from model inputs assuming a stable epidemic, except for Amsterdam where additional data were available, suggesting a decreasing PWID population size and declining incidence.

In sites with opioid and methamphetamine/amphetamine injecting, we assume that the baseline risk of HCV transmission is the same for all PWID. There is an equal NSP coverage across both types of injectors, but only opioid users can be recruited into OST.

In all but four sites (Czech Republic, Finland, Sweden, and Norway), HCV treatment of PWID was modelled only among

Results

Baseline HCV treatment rates

Chronic HCV treatment of PWID started at different times across the sites, ranging from 1997 in Slovenia to 2009 in Norway, with very few PWID having been treated in Finland. In Fig. 2, the percentage of chronic HCV prevalent cases among PWID that were treated in 2015/2016 based on data from each site is shown. They varied from <0.1% in Finland to 0.5–2% in Sweden, Denmark, Belgium, Norway, and Slovenia.

To consider the effect of uncertainty within the underlying parameters, we performed a linear-regression analysis of the disease prevalence of the relative decrease in chronic HCV prevalence between 2016 and 2026 on current treatment rates. The relative decrease in chronic HCV prevalence generated by the model was calculated by each parameter of each model outcome was calculated by each parameter of each model outcome was calculated.

For further details regarding the materials used, please refer to the Supplemental Information.

Uncertainty analysis

We used the model to project the change in prevalence and incidence between 2016 and 2026 when current treatment rates with DAAs remain constant is <5%. In these sites, the median increase in chronic HCV prevalence after 10 years if the current treatment coverage (if not already achieved) is 1.6. Impact projections either assumed that current coverages of OST and NSP are maintained, or OST and NSP are scaled-up to 80%.

Model projections and analyses

Data on PWID treatment numbers for each site were scaled to give a rate per 1,000 PWID, as well as the percentage of chronic HCV infections treated annually at baseline (2015/16) and 10-year scale-up of PWID treatment numbers. We determined the annual impact of treatment on the total PWID population size, we can easily compare the differences.

Fig. 2. Percentage of estimated PWID with chronic HCV infections treated annually at baseline (2015/16) and 10-year scale-up. This equates to a relative decrease of 10% at each site (see Supplemental Information).
If all sites switched to DAAs with the current treatment rates and concurrently increased OST and NSP coverage to 80%, the model projects a reduction in prevalence in all sites. This reduction is from <20% in Finland (17.6% [10.0–27.9%]) and Hamburg (19.5% [11.7–27.6%]), 30–50% in Scotland, Sweden, France, Norway, Denmark, and Belgium, to >50% in Czech Republic and Amsterdam, and >75% in Slovenia. The differential benefit of scaling-up OST and NSP alongside treatment on reducing chronic HCV prevalence ranges from >10 to <1.5 times because of baseline coverage. For example, in Finland, Sweden, and Belgium, scaling-up OST and NSP with the current HCV treatment rates reduces chronic HCV prevalence ranges from >10 to <1.5 times because of baseline coverage. For example, in Finland, Sweden, and Belgium, scaling-up OST and NSP with the current HCV treatment rates reduces chronic HCV prevalence in 10 years by 17.1%, 31.1%, and 48.4%, respectively, compared to 0.1%, 1.8%, and 4.4% reduction without OST and NSP scale-up. In contrast, there is only a small projected improvement in Amsterdam and Czech Republic, which already have high coverage of OST and NSP (Tables S1a–S1k). Other sites are projected to improve reductions in chronic HCV prevalence from two to three times (Slovenia, Hamburg, and Scotland) and five to six times in France, Denmark, and Norway (Table S3).

Switching to DAAs with treatment rate doubled
For sites with high baseline chronic prevalence (>55% at baseline) and low treatment rates (<1% of chronic infections treated at baseline) (e.g. Sweden and Finland), doubling the DAA treatment rates has little effect on the projected prevalence in 2026 (0.4% [0.3–0.6%] and 5.2% [3.3–10.4%] relative decrease, respectively) if OST and NSP are maintained at current coverage. For sites with moderate chronic prevalence (30–50% at baseline) and <2.5% of chronic infections being treated annually in 2015/2016 (Belgium, Denmark, Hamburg, Norway, and Scotland), doubling the DAA treatment rates could reduce chronic HCV prevalence from 11.6% relative decrease (Belgium) up to 23.5% (Scotland).

France has a moderate chronic prevalence (47.3%) at baseline and high initial treatment rate (4.5% [2.4–8.3%] of all chronic infections treated annually). When their treatment rate is doubled with DAAs, this yields a greater relative decrease in chronic prevalence than other sites with moderate prevalence (36.4% [16.7–85.5%]). The credibility intervals are wide because of uncertainty in the estimates of HCV treatment rates.

In Czech Republic and Slovenia, doubling the DAA treatment rates is projected to reduce chronic prevalence by >90% (Fig. 3), and in Amsterdam by 55.8% (32.8–69.6%).

Increasing OST and NSP to 80% coverage and doubling the DAA treatment rates are projected to reduce chronic prevalence between 17.9% (10.3–28.2%) in Finland and 99.5% (91.8–99.9%) in Slovenia. In sites with high baseline treatment rates (Czech Republic and Slovenia), the decrease in prevalence is primarily caused by doubling treatment rates (97.3% and 91.6% decrease in Czech Republic with and without scaled-up OST and NSP, respectively, and 99.5% and 97.4% in Slovenia). For sites with low baseline treatment rates and low coverage of OST and NSP, it is the increase in OST and NSP that drives the decrease in chronic prevalence rather than the doubling in treatment rates. In Finland, the decrease changes from 0.4% to 17.9% when
additionally scaling-up OST and NSP, from 5.2 to 35.5% in Sweden, and from 11.6% to 55.6% in Belgium.

**DAA treatment rate 50 per 1,000 PWID**

Increasing the annual DAA treatment rates to 50 per 1,000 PWID with the current OST and NSP coverage leads to substantial reductions in chronic HCV in all sites (Fig. 3). In the high-prevalence sites of Finland and Sweden, chronic prevalence reduces by about half by 2026. Conversely, chronic HCV prevalence decreases by 70% or more in most moderate-prevalence sites (Belgium, Hamburg, Scotland, Norway, and Denmark). In France, however, the decrease is smaller and more uncertain (47.6% [21.7–73.8%]). In low-prevalence settings (Czech Republic and Slovenia), chronic prevalence is projected to decrease by around 99% by 2026.

In projections with OST/NSP scale-up to 80%, prevalence decreases by more than three quarters in all sites, with 7/11 sites (Scotland, Denmark, Norway, Belgium, Amsterdam, Czech Republic, and Slovenia) projecting a decrease of >95%.

**HCV incidence among PWID**

Baseline projections of incidence before 2015 agree with observed incidence estimates where data were available (Supplementary materials). Projected changes in incidence from 2016 to 2026 are shown in Figs. S2 and S3, without and with scale-up of OST and NSP to 80% coverage using DAs. HCV incidence is projected to remain largely unchanged with the current OST and NSP coverage in all but three sites if the current HCV treatment rates are maintained using DAs. However, if OST and NSP are scaled-up to 80% coverage, projections estimate a relative decrease in incidence of over 35% at all sites.

The treatment number per 1,000 PWID required in 2016/2017 to reduce incidence to 2 per 100 pyr (2%) among PWID by 2026 with and without scale-up of OST and NSP to 80% coverage is shown in Fig. 5. In Amsterdam, an incidence of 2% (1–3%) was already estimated in 2016, and so just switching to DAs ensured an incidence <2% by 2026 in 99% of model runs. In Slovenia, just switching to the new DAs and maintaining the current treatment rates are likely to decrease incidence to <2% by 2026 (projected by 78% of model fits), with an increase in treatments rates by 20% being needed to ensure this impact in the other 22% of model fits. In Czech Republic, switching to DAs would achieve 2% incidence in <10% of model fits. Increasing the current treatment rates by 43% over all model runs would ensure the decrease. In all other sites, a substantial increase in HCV treatment rates (in the absence of any increase in OST and NSP coverage) is needed to reduce HCV incidence to 2%. This ranges from three to five times the current treatment rates in France and Scotland, to between six and nine times in Hamburg, Norway, Denmark, Belgium, 17 times in Sweden, and 200 times in Finland. If OST and NSP are scaled-up to 80% coverage, maintaining the current treatment rates is sufficient to achieve an incidence of 2% in 2026 in Amsterdam and Slovenia (100% of model fits), may achieve this impact in Belgium and
Czech Republic (84% and 50% of model fits), but is unlikely to (<10% of model fits) in other settings. Alongside increased OST and NSP, France, Denmark, Norway, Scotland, Hamburg, Sweden, and Finland would need to scale-up their baseline treatment rates by 2.2-, 2.8-, 2.8-, 3.6-, 4.7-, 10.3-, and 159-fold, respectively. This is 20–60% less than if OST and NSP had not been scaled-up.

Uncertainty analysis
The sensitivity analysis indicates that, for most sites, uncertainty in three main factors contributes to variation in the relative decrease in chronic prevalence and incidence between 2016 and 2026 when treatment rates are doubled, but with differing levels of influence between the sites (Fig. S4). The PWID population size contributes 34–63% of the variation in Finland, Belgium, Scotland, Slovenia, and Norway, and 80% in Sweden, whilst the prevalence estimates contribute 32–53% of the variation in five of the sites (Slovenia, Belgium, Czech Republic, Denmark, and Hamburg). The duration of injection is most important in Amsterdam, contributing 85% of the variation, but also contributes 25–48% in Scotland, Hamburg, Denmark, Norway, Belgium, and Finland. In France, the estimated treatment rate contributes 80% of the variation.

Discussion
Main findings
Treatment scale-up is needed to achieve observable reductions in chronic HCV prevalence among PWID in most sites in Europe, even with new DAAs. Doubling the DAA treatment rates may lead to observable reductions (12–24% decrease) in chronic prevalence by 2026 in Belgium, Denmark, Hamburg, Norway, and Scotland; but not in Finland or Sweden. Exceptions include Czech Republic, Slovenia, and Amsterdam, which, at current HCV treatment rates, are projected to reduce chronic HCV prevalence from a third to a half by 2026. This is because of the low or decreasing prevalence of infection in these settings. Alternatively, increasing OST and NSP coverage to 80% with the current HCV treatment rates would reduce chronic HCV prevalence by 17–20% in Finland and Hamburg, and 30–79% in all other sites. Reducing HCV incidence to <2% by 2026 requires little action in Amsterdam, Czech Republic, and Slovenia, whereas in Belgium, Denmark, Hamburg, Norway, and Scotland it will require at least a fivefold increase in the current HCV treatment rates, or 1.8– to 4.7-fold if OST and NSP are scaled-up to 80% coverage.

Strengths and limitations
Our model projections and their interpretation are influenced strongly by uncertainty in the parameters and evidence base. First, we collected information from a range of sources and obtained data not routinely collected across Europe (e.g. number of PWID treated for HCV). Unfortunately, data collection was inconsistent across sites, particularly estimates of PWID population size, which were used to estimate HCV treatment rates. Reliable PWID population-size estimates are difficult to obtain. Except for Amsterdam where evidence suggests a falling population we had to assume stable populations.
Second, uncertainty in the chronic HCV prevalence among PWID contributed substantially to the uncertainty in our projections, with estimates generated from a diverse range of sources and rarely (except for Scotland) from ongoing community-based surveillance.\textsuperscript{6,30}

Third, the duration of injecting drug use is difficult to estimate precisely and contributed to model uncertainty. We sampled the average injecting duration from a range extending from 6 to over 20 years. In the absence of clear evidence, we also assumed that opioid and methamphetamine injectors had similar durations. If the true duration is towards the higher end of our ranges, scaling-up HCV treatment will have a greater impact on transmission. If towards the lower end, scaling-up OST and NSP will have a greater contribution on reducing transmission.\textsuperscript{10}

Fourth, DAA SVRs for PWID in "real world" settings are yet to emerge, and so we assumed a range of 85–95%.\textsuperscript{31,32} Given the short treatment duration and early treatment of a predominantly mild disease, it is likely that SVRs will be very high. However, it is possible that, as treatment is scaled-up among more vulnerable PWID, the SVR may reduce. In general, the impact of HCV treatment in our projections is relatively robust to variations in SVR. However, an uncertainty in SVR becomes more influential in settings with lower chronic prevalence and higher HCV treatment rates. Furthermore, we assumed that PWID who had either cleared HCV spontaneously or after successful treatment had the same risk of reinfection as the susceptible population of PWID i.e. the per capita transmission probability of reinfection was the same as for primary infection. There is some evidence to suggest that previous spontaneous clearance could result in higher rates of clearance for subsequent reinfection.\textsuperscript{22}

However, similar data surrounding spontaneous clearance of reinfections after SVR do not exist. Infrequent testing intervals can contribute bias, as some reinfections may go unnoticed.\textsuperscript{22,33}

Observational studies have reported that reinfection after SVR can be of a similar, higher, or lower rate than the background rate of infection,\textsuperscript{34–38} indicating uncertainty in the evidence. However, if the reinfection risk was lower than the primary infection for people achieving SVR, or the spontaneous clearance is higher for reinfections, then our model projections represent conservative estimates for the number of treatments needed to reduce prevalence and incidence across the different sites.

Fifth, we recorded substantial differences in coverage of OST and NSP between sites that are incorporated into the baseline model. In subsequent intervention scenarios, we either considered no scale-up of these interventions, or assumed their scale-up to 80% coverage. This optimistic scenario may overestimate the likely impact of what could be achieved from scaling-up OST and NSP, although some of our sites demonstrate such coverage is possible. However, even if this scale-up is possible, it is unlikely that it would be achieved quickly, and so these projections may overestimate the real reduction in HCV that could be achieved from scaling-up OST and NSP.

Sixth, the model does not incorporate information on HCV case-finding and any future difficulty in diagnosing and treating PWID with chronic HCV when HCV transmission and prevalence have fallen to low levels. However, this limitation will only affect a small number of the most optimistic model projections.

Seventh, we have not modelled HIV co-infection, which varies across Europe and may impact both on linkage to services and morbidity outcomes.

Finally, we assume no change in injecting-risk behaviour following HCV treatment—apart from through exposure to OST and NSP, which is also included prior to HCV treatment. If injecting risk was reduced following treatment,\textsuperscript{19} our assumption provides conservative projections of impact.

Implications and comparisons with other literature

Multiple studies in specific countries and across Europe have used statistical and mathematical model projections to suggest that new DAA treatments need to increase to reverse trends in end-stage liver disease.\textsuperscript{40–44} However, to project impact on HCV transmission, a dynamic transmission model that can track both reinfection and prevention of future infections is required, alongside information on the number and proportion of individuals from key populations, like PWID treated for HCV infection. Consequently, there are fewer analyses that project impact on HCV transmission.

An earlier study revealed a two- to threefold difference in chronic HCV prevalence and four- to fivefold difference in baseline HCV treatment rates in seven cities in the UK.\textsuperscript{45} We also found considerable heterogeneity between sites in Europe. For example, the Czech Republic and Slovenia both have baseline chronic prevalence of <30%,\textsuperscript{25,46,47} whilst in Finland and Sweden it is over 55%. Treatment rates also varied two- to threefold. At baseline, 8/11 sites had low treatment rates (<10/1,000 PWID treated annually), whereas France had a much higher treatment rate (21/1,000 PWID treated annually). This is a consequence of the high access to HCV treatment in France compared to other countries.\textsuperscript{41} In this study, a greater decrease in prevalence for Amsterdam is shown than was projected in other studies.\textsuperscript{15,48} However, this could be caused by differences in modelling the decreasing epidemic to achieve the incidence estimate, and differences modelling the PWID population and transmission dynamics.

The lack of ongoing surveillance data, including PWID prevalence and HCV treatment rates among PWID, in many European settings and comparable indicators between countries is important and a public health concern. Using our model projections, it was shown that scaling-up OST and NSP combined with switching to DAAs with comparatively small increases in the number of PWID treated could generate substantial observable reductions in HCV prevalence in several sites. However, robust HCV surveillance data among PWID were not always available and chronic HCV prevalence was uncertain. To ensure that empirical evidence of the impact of HCV treatment as prevention can be generated, it is important that more attention is given to establishing robust surveillance systems to reduce the uncertainty surrounding chronic HCV prevalence among PWID. The potential and relative costs of introducing effective HCV surveillance are trivial compared to the costs of HCV treatment, and need to be encouraged across Europe.

Conflict of interest

NM, MH, and PV have received unrestricted research grants from Gilead unrelated to this work, and honoraria from MSD. HM is a consultant/advisor for AbbVie and Gilead and has received speaker fees from AbbVie, Gilead, MSD, and Medivir. MP has served as a speaker and has worked on several research projects unrelated to this study for which her institute received unrestricted grants from Gilead, Roche, MSD, and AbbVie.

Please refer to the accompanying ICMJE disclosure forms for further details.
Authors’ contributions
All authors contributed to interpreting the results, writing, and editing the paper. HF undertook modelling supervised by PV, MH, and NM, and drafted the paper. MH, NM, and PV conceived the study with support from all co-authors.

Acknowledgements
The study was funded by the European Commission Drug Prevention and Information Programme [JUST/2013/DNIP/AG/4812]. In addition, the authors acknowledge support from the National Institute for Health Research (NIHR) Health Protection Research Unit in Evaluation of Interventions at the University of Bristol in partnership with Public Health England. NM, PV, and MH were supported by the National Institute on Drug Abuse (grant number R01 DA037773-01A1). NM was additionally supported by the University of California, San Diego, Center for AIDS Research, a National Institutes of Health-funded program (grant number P30 AI036214). The views expressed are those of the author(s) and not necessarily those of the National Health Service, the NIHR, the Department of Health, or Public Health England. VM: institutional support number PRVOUK-P03/LF1/9 and project number LO16111 with financial support from the MEYS under the NPU I programme.
