Abstract

Purpose—To investigate the twin testosterone transfer (TTT) hypothesis by comparing early-life mortality risks of opposite-sex (OS) and same-sex (SS) twins during the first 15 years of life.

Methods—We performed a population-based cohort study to compare mortality in OS and SS twins. We included 68,629 live-born Danish twins from 1973 to 2009 identified through the Danish Twin Registry and performed piecewise stratified Cox regression and log-binomial regression.

Results—Among 1933 deaths, we found significantly higher mortality for twin boys than for twin girls. For both sexes, OS twins had lower mortality than SS twins; the difference persisted for the first year of life for boys and for the first week of life for girls.

Conclusions—Although the mortality risk for OS boys was in the expected direction according to the TTT hypothesis, the results for OS girls pointed in the opposite direction, providing no clear evidence for the TTT hypothesis.

Introduction

It is well known that boys have higher risk of infant mortality and morbidity than girls [1,2]. Sex differences in mortality have been explained by a combination of biological, social, and environmental factors, but lifestyle and behavioral factors are less likely to explain sex difference in infant mortality [3]. Studies of animal models find that males exhibit reduced immune responses and increased intensity and prevalence of infections compared with females [4]. These sex differences may reflect the immunosuppressive effects of testosterone, as well as the positive effects of progesterone and estradiol on immune responses [4,5]. Whether these findings apply to humans is unknown [1], but there is evidence that girl infants have lower mortality from infections [6] and respiratory conditions [7] compared with boys. It is hypothesized that the male disadvantage begins in utero [8], where the gonadal steroid production differs between the sexes [3].

Twin studies offer unique opportunities to investigate mechanisms underlying sex differences. There is evidence suggesting that male sex hormones could influence the female fetus in opposite-sex (OS) twins. For instance, studies in mammals have found that female fetuses positioned between two males are likely to express masculinization of anatomical, physiological, and behavioral traits in adult life [9]. Sex hormones are lipid soluble steroids capable of crossing fetal membranes [10]. The twin testosterone transfer (TTT) hypothesis states that human fetuses gestated with a male co-twin are masculinized in development, which may be due to the exposure of prenatal androgens [11]; however, the evidence remains inconclusive (for reviews, see [11,12]).

Hence, early-life mortality risks in OS and same-sex (SS) twins may also differ due to zygosity differences. OS twins are always dizygotic (DZ), whereas SS twins are either monozygotic (MZ) or DZ. A large part of MZ twins (70%–75%) are monochorionic (MC), sharing only one placenta, and the remaining part has completely separate placentas and membranes (dichorionic [DC]) [13]. MC twins are at increased risk for perinatal mortality and morbidity compared with DC twins [14].

The literature comparing OS and SS twins with regard to early-life mortality risks is limited and inconsistent, but higher infant mortality for SS boys than for OS boys [15–17] and adverse outcomes including increased respiratory morbidity and higher mortality for OS twin girls in agreement with the TTT hypothesis have been reported [18–20]. Our study using data on a sample of 68,629 Danish twins aims to compare mortality in twin boys and girls and in OS and SS twins by age and over time within the first 15 years of life.

Materials and methods

Material

This study consists of all twins born in Denmark during the period 1973–2009. The twins were identified through the Danish Twin Registry [21,22]. The Danish Twin Registry has collected data on twins including zygosity of SS twin pairs born up to 2000, which is based on questions about the degree of co-twin similarity [23]. However, both twins have to be alive beyond infancy to have their zygosity assessed by questionnaire and therefore zygosity
is generally available only for twin pairs surviving infancy [21]. All twins both live-born and stillborn have been identified through the Danish Medical Birth Registry since 1973 [24]. For these twins, information about the personal identification numbers for the infant and the mother, information on deaths among live-born twins, as well as information on emigrations came from the Danish Civil Registration System [25]. Information on causes of death was obtained from the Danish Registry of Causes of Death [26]. Information on maternal education came from the Danish Education Registers [27], and information about birth weight was obtained from the Medical Birth Registry [28]. In total, 68,629 live-born twins were eligible for analyses (Table 1). For the birth cohorts 1973–1996, information about stillborn twins was available for 34,736 twins.

**Variables**

Possible confounders in this study were year of birth, maternal education, and maternal age. Year of birth ranged from 1973 to 2009 and was stratified into decades (birth cohorts: 1973–1979, 1980–1989, 1990–1999, 2000–2009). Maternal education refers to the highest completed education until year 2012. The categorization of education was based on the International Standard Classification of Education [29]. Three groups were distinguished: primary and lower secondary (<10 years), upper and postsecondary (10–12 years), and tertiary (>12 years). Maternal age at delivery was categorized as younger than 20 years, 20–34 years, and 35 years and older. Birth weight was considered an intermediate factor in the association between OS/SS twins and mortality. However, all analyses were repeated including birth weight, and the results were similar (not shown). Based on age-at-death, we generated four separate risk periods according to the definitions of the categories of infant deaths: early neonatal deaths (0–7 days), late neonatal deaths (8–28 days), postneonatal deaths (29–365 days), and child mortality (1–15 years) [30].

**Statistical analyses**

Analyses of differences in categorical baseline characteristics (emigration and maternal education) for OS and SS twins were performed by $\chi^2$ tests. Differences in continuous background variables (maternal age and birth weight) were investigated using $t$ tests. Relative risks (RRs) for child mortality (0–15 years) for each of the possible confounders were calculated stratified by sex applying log-binomial regression both crude and adjusted for the other covariate. All estimates were adjusted for decades. To analyze the associations of mortality between girls and boys and between OS and SS twins, we used piecewise stratified Cox regression, adjusting for the nonindependence of twins in a pair [31]. The twins were followed up for 15 years or until July 1, 2013, whichever came first. All associations were expressed as hazard ratios (HRs) with 95% confidence intervals (CIs). The Cox proportional hazards assumption was fulfilled in all risk periods. Mortality HRs, taking into account emigrations as censoring, were reported including adjustment for decades, crude, and adjusted for maternal age and education. Analyses of sex differences were done within all twins as well as within intact OS twin pairs. All analyses were repeated within each decade, and analyses of OS and SS twins were conducted separately for each sex. Cause-specific mortality was classified according to the main groups in the International Classification of Disease 8 and 10 (9 was never used in
Denmark). The associations of OS/SS twins with cause-specific mortality were investigated using $\chi^2$ test.

We performed two sensitivity analyses regarding zygosity: First, we included all twins with unknown zygosity (UZ) in the MZ and same-sex dizygotic (ssDZ) twin groups, respectively, and compared these twin groups with the OS twins. Second, the UZ twins were randomly distributed (50:50) between the MZ and ssDZ twins. These groups were then compared with the OS twins and this analysis was repeated 10 times with this random distribution of the UZ twins. Moreover, differences in the risk of stillbirth and perinatal mortality between girls and boys and between OS and SS twins born between 1973 and 1996 were investigated. This was done using log-binomial regression estimating RRs and 95% CIs. A stillbirth was defined as a delivery of a dead fetus at 28 or more completed weeks of gestation. Perinatal mortality was defined as stillbirths and deaths of live-born infants within the first seven days of life.

We estimated the overall mortality (0–15 years) for each decade for live-born boy and girl twins using Kaplan-Meier estimation, which were performed stratified by OS/SS twin status. In addition, we estimated HRs and 95% CIs for the differences in mortality between the different decades through a stratified Cox proportional hazards analysis for OS and SS twins as well as for all twins.

**Results**

A total of 1933 deaths of all causes were observed in 68,629 twins (Table 1). Differences in neonatal deaths (early and late), postneonatal deaths and child mortality for live-born boys and girls, and OS and SS twins are shown in Table 2. We found that boys had significantly higher mortality than girls at all ages. For stillbirth and perinatal mortality, the significant sex differences were verified (Table 3). When we compared the mortality for boys and girls within OS twin pairs, the significant differences vanished in all age groups.

Among live births, OS twins had significantly lower mortality than SS twins for both sexes. For boys, a significantly lower mortality for OS than SS twins was found for both early neonatal deaths (HR: 0.66; 95% CI: 0.55–0.79), late neonatal deaths (HR: 0.62; 95% CI: 0.40–0.96), and postneonatal deaths (HR: 0.63; 95% CI: 0.43–0.92). For girls, the difference was only found for early neonatal deaths (HR: 0.74; 95% CI: 0.61–0.90) (Table 2 and Fig. 1). Adjustments for maternal age and education did not change the effect estimates to any substantial degree (Table 2).

Of the six groups of death causes (Supplementary Table 1), we did not find significant differences between OS and SS twins except from higher risk of external causes (injuries) for OS compared with SS girls (3.6% vs. 0.9%, $P = .007$). However, when comparing OS and SS twins regarding infectious and respiratory diseases separately, we found that OS boys had lower mortality from infectious diseases compared with SS boys (0.4% vs. 2.5%, $P = .032$) (results not shown).

Both sensitivity analyses confirmed a lower mortality for OS compared with ssDZ twins. All HRs were below 1 for both sexes. For boys, all associations were significant in the neonatal
period and the HRs ranged between 0.61 and 0.73. For girls, the HRs ranged between 0.74 and 0.87, but only few associations were significant (results not shown).

The analyses of stillbirths confirmed a lower mortality for OS than for SS twins of both sexes, RR: 0.48 (95% CI: 0.36–0.65) for boys and 0.42 (95% CI: 0.29–0.59) for girls. The same pattern was found when analyzing perinatal mortality (Table 3).

Overall mortality within the first 15 years of life has decreased during the last 4 decades in Denmark for OS and SS twins of both sexes. For live-born boys, the mortality decreased from 5.0% to 1.9% for OS and from 7.2% to 2.3% for SS twins. For girls, the mortality decreased from 4.0% to 1.7% for OS and from 4.6% to 1.9% for SS twins (Figs. 2 and 3). From the 1990s to the 2000s, the decrease in mortality was only significant for SS boys, and for OS boys, a tendency was found in the opposite direction toward higher mortality with time (HR: 1.23; 95% CI: 0.90–1.69) (Supplementary Table 2).

The raw associations between the potential confounding variables and mortality showed an inverse association between maternal education and child mortality for both sexes, however, only significant for twin girls whose mothers had the lowest education. Maternal age was not significantly associated with mortality for twins; however, a tendency was indicated toward higher mortality among twins with mothers below age 20 and a lower mortality for twins with mothers above age 35 (Supplementary Table 3).

Discussion

A large population-based cohort study was used to compare mortality in OS and SS twins within the first 15 years of life. We confirmed the known sex differences in mortality. For live-born boys, the results demonstrated a significantly lower mortality for OS than for SS twins in the neonatal (early and late) and postneonatal periods. There are at least two possible explanations for this: first, the inclusion of the MZ twins in the SS twin group; second, lower exposure to testosterone in utero for OS than for SS boys. For girls, we found similar mortality between live-born OS and SS twins, except that OS girls had the lowest mortality within the early neonatal period. The risk of stillbirth was significantly lower for OS than for SS twins for both sexes. An overall decrease in mortality was observed for both OS and SS twins during the last 4 decades in Denmark.

The present study agreed with previous twin studies reporting higher mortality for male-female than for female-female twins [15–17]. However, we found that within OS twin pairs, sex-related differences in mortality were much less pronounced with no significant mortality differences between girls and boys, also consistent with earlier reports [17,32].

The lower perinatal mortality for OS than for SS twins may at least partly be due to the MZ twins being in the SS twin groups. One of the major findings from the East Flanders Prospective Twin Survey, where perinatal data such as chorion type and zygosity are established at birth, is that MZ twin pairs have a significantly higher risk of perinatal mortality than DZ twin pairs; however, the difference was limited to the MC subgroup and was especially the case before birth [14]. A large Danish study comprising 2043 twin pregnancies with ultrasound chorionicity determination before 15 weeks of gestation...
confirmed a higher mortality rate for MC compared with DC twins, but this difference leveled off after 24 weeks of gestation and neonatal mortality was not correlated with chorionicity [33]. A study of 4191 OS twins and 10,875 SS twin pairs born in Sweden from 1973 to 1989 found that pregnancy loss was twice as high in SS compared with OS twins [34]. In accordance with these results, we found the largest difference in mortality between OS and SS twins for stillbirths.

Another reason for the better early-life survival for OS than SS boys may be lower exposure to prenatal testosterone. Transfer of testosterone is assumed based on animal studies which have demonstrated that any fetus, independent of sex, located between two male fetuses, has a higher concentration of testosterone than a fetus located between two females [12]. There are no studies of amniotic fluid testosterone levels from OS and SS twin pairs [35], and studies comparing OS with SS females have shown inconclusive results with the most consistent evidence to support the TTT hypothesis coming from studies of perception and cognition [11]. Several studies that have investigated co-twin effects in males have failed to identify differences between OS and SS male twins, for example, with regard to tooth size [36], academic performance [37], and cancer [38]. However, animal studies find that males exhibit reduced immune responses and increased intensity and prevalence of infections compared with females [4], and in humans, there is evidence that girl infants have lower mortality from infections [6] and respiratory conditions [7] compared with boys, which may reflect the immunosuppressive effects of testosterone [4,5]. Therefore, deaths with an infectious and respiratory disease underlying death cause are particularly interesting. We found that SS boys had higher mortality from infectious diseases compared with OS boys. Moreover, the better survival for boys with a girl co-twin persisted during the first year of life. These findings may provide evidence for the TTT hypothesis. Our results showing better early-life survival for OS than for SS boys were in line with the recent Swedish cohort study [17]. For girls, we did not find any significant differences between OS and SS twins in the hypothesized direction according to the TTT hypothesis, not either in the sensitivity analyses where the UZ twins were randomly distributed between the MZ and ssDZ twins. On the contrary, OS girls had significantly better survival than SS girls, although the mortality of OS girls was not significantly different from that of their twin brothers.

In agreement with previous studies [39,40], we found that the mortality risk has declined steadily for twins during the last decades. A study from Japan found that the decline in perinatal mortality of OS twins has been slower than that of SS twins since 1984 [41]. A study from the USA found that the perinatal mortality decreased for MZ twin pairs throughout the period 1980–2004, whereas the mortality for the DZ twin pairs decreased until the mid-1990s and increased slightly thereafter [42]. The authors suggest that advancing maternal age and increasing use of fertility treatments may be a reason for the stalling of the decline in perinatal mortality rates. Also, we observed no decrease in mortality for live-born OS twins between the 1990s and the 2000s.

The major strengths of this study are the availability of reliable mortality data from a large population-based register for all twins born 1973–2009 with complete follow-up. To our knowledge, this is the largest study of mortality risks among OS and SS twins. We were also able to analyze stillbirth and perinatal mortality for a large subgroup of OS and SS twins.
The important limitation of this study was the lack of data on twin zygosity and chorionicity. No information on zygosity was available for 51.4% of the live-born SS twins. OS twins are by definition DZ (i.e., all OS twins also those who dies shortly after birth are included in this group). If we exclude the UZ twins, the SS twin group consists exclusively of twin pairs in which both survived infancy and hereby could have their zygosity determined. Therefore, twins with known zygosity are not comparable with OS twins and bias will be present in the associations toward higher mortality for the OS twins. Therefore, it was not possible to evaluate whether ssDZ twins and OS twins have similar mortality, which is the most valid comparison of the TTT hypothesis.

In summary, this large study of Danish twins confirmed a higher mortality for twin boys than twin girls and found significantly lower perinatal mortality for OS than for SS twins of both sexes. This may at least partly be due to the inclusion of MZ twins with higher perinatal mortality in the SS twin groups. The results for OS girls were in the opposite direction as predicted by the TTT hypothesis, whereas the OS-SS comparison for boys regarding mortality and cause of death pattern provided some evidence for the TTT hypothesis. Future studies with the possibilities of including information on zygosity and/or chorionicity should investigate differences between OS and ssDZ twins only.
