Objective

The objective of this study was to determine whether Tick-borne Encephalitis virus (TBE-virus) foci could exist outside the known endemic areas in Denmark. To explore this, we performed a high intensity sero-prevalence study of TBE-virus throughout Denmark using roe deer (C. capreolus) as sentinel. Presented here are the preliminary results.

Introduction

Tickborne encephalitis (TBE) is considered endemic on the Danish island of Bornholm in the Baltic Sea, and was for many past decades thought to represent an isolated focus in Denmark (1-5). However, seroprevalence studies of TBE-virus in roe deer and dogs conducted in the years 2002-2009 indicated that TBE-virus existed in parts of Denmark from where no human cases had been reported (6-7). This was recently (2009-2011) further supported by two clinical cases of TBE in humans living and working in the forest “Tøkkekeb Heng” and in ticks from the same area (8-9).

Objective

The objective of this study was to determine whether Tick-borne Encephalitis virus (TBE-virus) foci could exist outside the known endemic areas in Denmark. To explore this, we performed a high intensity sero-prevalence study of TBE-virus throughout Denmark using roe deer (C. capreolus) as sentinel. Presented here are the preliminary results.

Method

Danish hunters were invited to participate during the regular hunting season of 2013-14. They were asked to obtain blood samples from roe deer when dressing freshly killed animals in the field, Photo 1. For each animal, location, sex, age, and degree of tick infestation were noted. Blood collection kits were distributed to the hunters by mail, and blood samples subsequently returned by mail to The Research Unit of Clinical Microbiology, University of Southern Denmark. From here the serum or preferably buffycoat was sent to the Department of Virology, Medical University Vienna where they were examined for the existence of TBE-virus specific antibodies by Neutralisation-test (NT-test).

Results

815 samples were collected. Analysis of 364 selected samples has so far yielded 51 NT-positive and 282 NT-negative roe deer*, Table 1. 31 samples could not be analysed due to toxic effect of the serum on the cell. The remaining 451 samples will undergo NT-testing at the Department of Virology, Medical University Vienna in the autumn of 2015. The positive samples span all of Denmark and include areas that have no past history of human TBE cases. Many positive samples originated from locations which also in previous sentinel studies have provided TBE-positive samples, but new possible TBE-virus foci have also appeared, Figure 2, shows the location of the TBE-positive roe deer (2013-2014) based on municipality.

Conclusions

These preliminary results support our hypothesis that TBE-virus exists in Denmark beyond the currently known foci on Bornholm and North Zealand, and that medical doctors in all of Denmark should keep TBE in mind when treating a patient with symptoms of encephalitis and a history of tick exposure.
