ABSTRACT

Objectives Poisoning is a frequent cause of admission to the emergency department (ED) and may involve drugs known to prolong the QT interval. This study aims to describe the prevalence of QTc prolongation among ED patients with suspected poisoning and to calculate the absolute and relative risk of mortality or cardiac arrest associated with a prolonged QTc interval.

Methods We performed a register-based cohort study, including all adult first-time contacts with suspected poisoning to the ED of two Swedish hospitals (January 2010–December 2014) and two Danish hospitals (March 2013–April 2014). We used propensity score matching to calculate HRs for all-cause mortality or cardiac arrest (combined endpoint) within 30 days after contact comparing patients with a prolonged QTc interval (≥450 ms men, ≥460 ms women) with patients with a QTc interval of <440 ms.

Results Among all first-time contacts with suspected poisoning that had an ECG recorded within 4 hours after arrival (n=3869), QTc prolongation occurred in 6.5%. The overall mortality after a 30-day follow-up period was 0.8% (95% CI 0.6 to 1.2), with an absolute risk of mortality or cardiac arrest in patients with QTc prolongation of 3.2% (95% CI 1.4 to 6.1). A prolonged QTc interval on arrival was associated with a HR of 3.6 (95% CI 1.0 to 12.2).

Conclusion In the ED, a prolonged QTc interval in patients arriving with suspected poisoning seems to be associated with a threefold increased risk of 30-day all-cause mortality or cardiac arrest.

INTRODUCTION

Poisoning is a frequent cause of admission to the emergency department (ED)1 2 and involves a variety of different drugs and substances. A wide range of drugs have been linked to QTc prolongation,3 which has been associated with all-cause mortality, cardiovascular death and sudden cardiac death.4–9 As an increased risk of mortality has been documented in patients treated with potential QTc prolonging drugs,10–13 one may hypothesise that the risk is even higher among poisoned patients. Therefore, cardiac monitoring is recommended in patients poisoned by potentially proarrhythmic agents and drugs that can lead to torsades de pointes.14

Only few studies have investigated the relationship between QTc prolongation and adverse outcomes in a population of undifferentiated poisoned patients.15 16 The absolute and relative risk of mortality and cardiac arrest associated to QTc prolongation in poisoned patients remains unknown. Therefore, we aimed to: (1) describe the prevalence of QTc prolongation found among patients with suspected poisoning in the ED; and (2) to investigate if QTc prolongation is associated with an increased risk of mortality or cardiac arrest within 30 days after arrival to the ED.

MATERIALS AND METHODS

Study design and setting

This is a register-based cohort study. The study is based on ED data from 1 January 2010 to
31 December 2014 from two Swedish hospitals (Skåne University Hospital, Lund, and Helsingborg Hospital) and from two Danish hospitals (Odense University Hospital and the Hospital of South West Jutland, Esbjerg) from 1 March 2013 to 30 April 2014. In both Denmark and Sweden, the healthcare systems are tax-funded, and all residents have free access to healthcare. The University Hospital Skåne has a contingency population of approximately 310,000, whereas Odense University Hospital covers a population of 290,000 people. The two regional hospitals have a contingency population of 250,000 people (Helsingborg) and 220,000 people (Esbjerg).

Selection of participants
We identified all adults (≥18 years) who arrived to the EDs with suspected poisoning. The contacts were eligible for the main analysis if they had a 12-lead ECG recorded within 4 hours after arrival. A missing QTc interval on the recorded ECG or a QRS duration of ≥120 ms were both reasons for exclusion. Patients with multiple contacts were included only at their first contact with suspected poisoning within the study period. Information regarding identification of patients with suspected poisoning is outlined in online supplementary appendix A.

Data sources
In both Denmark and Sweden, all residents have a unique personal civil registration number, which allows cross-linkage at personal level between databases. We extracted data from several registries: the logistic systems in the ED at the Region of Southern Denmark,17 and Region of Skåne, the electronic central ECG databases at Region of Southern Denmark and Region of Skåne, the Danish National Patient Registry18 and Region of Skåne Healthcare databases, the Danish National Prescription Registry,19 the Swedish Pharmacy Registry,20 and finally The Danish Civil Registration System21 and the Swedish Population Register.22 Further information regarding the data sources is provided in online supplementary appendix A.

ECG measurements and definitions
The QT interval was measured at the first ECG recorded after contact to the ED. All the QT intervals were calculated automatically as a median value and stored in either MUSE Cardiology Information System (GE Healthcare) or Philips Diagnostic ECG. The GE Marquette 12SL ECG Analysis Program provided QTc intervals for ECGs recorded in MUSE.23 ECGs recorded by Phillips were analysed by the DXL-algorithm.24 Only QT intervals corrected for heart rate (QTc) was used in our analysis. For correction, we chose the Framingham Formula (QTcFramingham = QT + 0.154 (1−RR)).25 Additional details about ECG measurements are outlined in online supplementary appendix B.

Exposure and outcome
Our primary outcome was a combined endpoint of all-cause mortality or cardiac arrest (defined in online supplementary appendix C.1) within 30 days from the day of arrival to the ED. All patients were followed for 30 days, including those transferred to another department. Patients who died in relation to cardiac arrest were classified as dead rather than cardiac arrests. The primary exposure was QTc prolongation, defined as a QTc of ≥450 ms for men and ≥460 ms for women.26 Patients with a normal QTc length were defined as having a QTc interval of <450 ms (men) or <460 ms (women).

Analysis
The prevalence of QTc prolongation overall and in relation to specific groups of poisoning was described in a cross-sectional description. In this description, we identified all patients with a discharge diagnosis of poisoning (International Classification of Diseases (ICD-10) codes T36*-T65*, F100*, F110*, F120*, F130*, F140*, F150*, F160*, F170*, F180* or F190* as a primary or secondary diagnosis). All patients, who had a discharge diagnosis of poisoning, were subdivided into five poisoning groups: (1) analgesics and drugs of abuse, (2) psychotropic drugs including drugs affecting the central nervous system, (3) organic and chemical substances, non-medical, (4) others and (5) multidrug (see online supplementary appendix C.2).

The association between QTc prolongation and all-cause mortality and cardiac arrest was evaluated using propensity score matching.27 28 We calculated a propensity score for all included patients by use of logistic regression with QTc ≥450 ms (men) or ≥460 ms (women) as the outcome (binary outcome). Patients with a QTc interval between 440–449 ms (men) and 440–459 ms (women) were excluded in the model to avoid near-overlapping ranges. The following possible confounders were included in the propensity score model: sex, age, comorbidity (measured as Charlson Comorbidity Index29 30), history of myocardial infarction or congestive heart failure (online supplementary appendix C.3 and C.4), prescription of QT prolonging drugs within 90 days (defined in online supplementary appendix C.5),31 heart rate and study centre. We performed a 1:2 parallel balanced nearest neighbour matching without replacement and with a calliper of 0.05.32 In the matched cohorts, 30-day mortality was modelled using Cox regression.

Statistics
The absolute risk of event in patients with suspected poisoning was calculated overall, for those with QTc prolongation and for those without QTc prolongation. In the propensity score matched cohort, the risk associated with QTc prolongation was estimated as HRs. We estimated 95% CIs based on a binomial distribution. To illustrate the impact of QTc prolongation on 30-day all-cause mortality or cardiac arrest, we generated a Kaplan-Meier failure curve.

In a sensitivity analysis, we restricted the material to individuals who were both suspected of being poisoned...
on arrival and received a discharge diagnose of poisoning. The prevalence of QTc prolongation and the propensity score analyses were repeated using the Bazett formula for QT correction.33

Statistical analyses were performed using STATA V.14.

The study was approved by the Danish Data Protection Agency (no. 2008-58-0035, journal nr. 15/21632) and The Danish Health Authority (no. 3-3013-1031).

Patient and public involvement
This was a study without contact to patients. All information was obtained through registers.

RESULTS
Characteristics of the study cohort
At the four hospitals, we identified a total of 6838 ED contacts with suspected poisoning. After exclusion of those aged <18 years (n=22), an ECG not recorded in an acceptable time-interval (n=1411), multiple contacts within the study period (n=1412), a missing QT interval (n=1) or QRS duration ≥120 ms (n=123), the final cohort comprised 3869 patients with suspected poisoning (48.0% men, median age 38) (figure 1). Of these, 69.2% (n=2676) had a discharge diagnose of poisoning.

Patients with a prolonged QTc interval were older, had more comorbidity and more commonly had a history of heart disease than those without QTc prolongation (table 1).

In addition, prescription of QT-prolonging drugs was more frequent in the group with a prolonged QTc interval. Among patients with a redeemed prescription of a single QT-prolonging drug, 7.5% had a prolonged QTc interval, whereas 8.8% of those taken two or more QT-prolonging drugs had a prolonged QTc interval. Among the included

patients, 6.5% (95% CI 5.9 to 7.4) had QTc prolongation, while the prevalence of severe QTc prolongation (≥500 ms) was 0.7% (95% CI 0.5 to 1.0). The prevalence of QTc prolongation in relation to specific groups of poisoning varied within the range 4.8%–6.2%, with the highest prevalence in the group categorised as ‘others’ (6.2%; 95% CI 4.8 to 8.7) (table 2).

*In the total cohort patients with a near-overlapping QTc interval (440–449 ms men, 440–459 ms women) are included (n=320). CCI, Charlson Comorbidity Index.

**Prognosis**

Overall, the 30-day risk of all-cause mortality or cardiac arrest was 0.8% (95% CI 0.6% to 1.2%, n=32). Among individuals with QTc prolongation (n=253), death within 30 days after contact to the ED occurred in seven patients, whereas one patient suffered from cardiac arrest. Among those with a normal QTc interval (n=3616), we found 24
events during the follow-up period. The absolute risk of event within 30 days was 3.2% (95% CI 1.4 to 6.1) and 0.7% (95% CI 0.5 to 1.0) for patients with and without QTc prolongation, respectively.

The propensity score analysis included 248 patients with a QTc of ≥450 ms (men) or ≥460 ms (women) matched with 496 patients with a QTc interval <440 ms. Acceptable balance of baseline variables was achieved (table 1). QTc prolongation was associated with a HR of 3.6 (95% CI 1.0 to 12.2) for 30-day all-cause mortality or cardiac arrest (table 3 and figure 2).

Subgroups and sensitivity analyses
Our results from the subgroup analysis are outlined in online supplementary appendix D. When restricting to those who also received a discharge diagnosis of poisoning, we found an overall 30-day risk of 0.7% (95% CI 0.4 to 1.1), and QTc prolongation yielded an overall HR of 10.5 (95% CI 1.2 to 90.0). When we corrected the QT interval with the Bazett formula, a total of 1112 patients had QTc prolongation (28.7%), which was associated with a HR of 1.0 (95% CI 0.2 to 5.5).

DISCUSSION
In this transnational cohort of patients with suspected poisoning arriving to the ED, QTc prolongation was common (6.5%). A prolonged QTc interval was associated with a threefold increased risk of 30-day all-cause mortality or cardiac arrest and an absolute risk of 3.2%.

This study has several strengths. First, this was a multicentre cohort study with data from two Swedish and two Danish EDs, which ensured a broad representability. Use of personal identification numbers in all contacts to the hospital system in Sweden and Denmark provides the possibility to follow individual patients in and out of hospital, and loss of follow-up or unmeasured registration of death did not occur.17–22 In addition, we implemented several
confounders in our propensity score model, and thus managed to control for these despite a low event rate. We included patients who were suspected for being poisoned on arrival to the ED. These patients do—in contrast to patients identified by their discharge diagnosis—represent the clinical situation at the door in the ED. At this point, the doctors have to decide whether to observe the patients using telemetry.

This study also has several limitations. First of all, the design was an observational design. The ECG measures were all automatic readouts, and we did not manually validate the length of the QT intervals. However, this method has been validated in a previous Danish study using the same technique, which showed a good overall agreement between manual QTc interval and the digital record of the QTc interval with a mean difference of 1.3 ms. Furthermore, we did not exclude ECGs with diagnoses complicating QTc measuring, for example, atrial fibrillation. We did not have information regarding previous ECGs, and we do not know if some patients had a previous ECG with QTc prolongation before arrival with suspected poisoning. The dose of drug or substance was unknown, and we were ignorant of the timing of the ECG recording in relation to peak drug concentration. The poisonings were not confirmed by blood samples or by urine tests but were extracted from predefined ICD-10 codes. In addition, administration of diuretics and possible electrolyte imbalance were unknown.

The small number of events was a limitation in its own and did not allow for meaningful subgroup analysis. Since cardiac arrest was identified based on hospital registration, an eventually event of unregistered cardiac arrest, where the patient survived, is not included as an event. The number of these events is believed to be small as registration of cardiac arrest is mandatory in both the Swedish and Danish healthcare system. With a small number of events, any miscounting of events would lead to considerable change in risk estimates. If we have overlooked one event of cardiac arrest who survived in the group of patients with QTc prolongation, it would increase the absolute risk from 3.2% to 3.6%, while the risk of event in the entire study population would increase from 0.8% to 0.9%.

The event rate in our cohort (0.8%) is in accordance with previous studies of poisoned patients (0.5%–1.2%). In contrast, the prevalence of QTc prolongation is substantially lower (6.5%) than in a previous study of unselected ED patients (35%). This is probably due to the choice of QT correcting formula. If the Bazett formula had been chosen for main analysis, the prevalence of QTc prolongation in our study population would have been 28.7%. It is of broad consensus that the more widely used Bazett formula tends to overcorrect at heart rates at 80–90 beats per minute and above resulting in a higher prevalence of QTc prolongation. As a high percentage of acute patients have tachycardia at arrival, this probably explains most of the difference between the occurrence of QTc prolongation in our study and in the study of unselected ED patients. The Framingham formula used in our study is considered superior compared with the more widely used Bazett formula.

The clinical impact of our findings is the difference in risk of all-cause mortality and cardiac arrest within 30 days in respect to QTc prolongation. We found an absolute risk of 0.7% in patients with suspected poisoning without QTc prolongation, whereas patients with a prolonged QTc interval have an absolute risk of 3.2%, which translates into an HR of 3.6 (95% CI 1.0 to 12.2). In the general population, a meta-analysis reported a pooled relative risk of 1.35 (95% CI 1.24 to 1.46) for long-term mortality in patients with QTc prolongation. A recent study including all patients who had an ECG recorded at the hospital for any reason reported QTc prolongation to be associated with a HR of 7.3 (95% CI 4.10 to 13.05) for 30-day mortality. Combined, these studies support the hypothesis that patients with a prolonged QTc are at increased risk. Whether this is directly linked to the increased QTc interval or due to other risk factors associated with a prolonged QTc remains unknown.

As demonstrated in our cohort, the prevalence of QTc prolongation is strongly associated to the correction formula. Furthermore, the difference between the HR calculated in the main analysis using Framingham (HR 3.6; 95% CI 1.0 to 12.2) versus the sensitivity analysis using Bazett (HR 1.0; 95% CI 0.2 to 5.5) is remarkable. We suspect that using the Bazett formula dilutes the association by including more patients at low risk as a result of overcorrection.

Despite the use of a propensity score model adjusting for several covariates, we cannot exclude residual confounding. From a clinical point of view, this means that the patients with a prolonged QTc probably need special care and attention. However, the needed care is not necessarily limited to telemetry and increased cardiac awareness. Of note, a ventricular arrhythmia with fatal outcome caused by drug-induced QTc prolongation would be expected to happen within a relatively short time-interval after exposure. This was not the case in our study with the first event occurring 3 days after contact (see figure 2). In addition, a QTc interval threshold for identification of patients in need of cardiac telemetry is not well established. Unfortunately, our cohort was too small to do further subdivisions of the QTc interval.

Ventricular arrhythmias, especially torsades de pointes, are feared consequences of QT prolongation and may be the cause of death in some poisonings. However, as torsades de pointes is a rare condition, it is unlikely to have influenced our results.

In this cohort of patients with suspected poisoning, 69.2% received a discharge diagnose of poisoning. This is in contrast to results from a previous Danish study, which found an agreement of 79% for suspected poisoning on arrival and a discharge diagnose of poisoning. In our cohort, only those who had an ECG recorded were included, and several common
poisonings, for example, alcohol intoxication, are usually not followed by ECG recording.

QTc prolongation was most frequent in the group of poisoning labelled ‘others’ (table 2). In this group, the ICD-10 code T50.9 for unspecified poisonings was given to the majority of the patients. These patients might have been too sick to tell about their poisoning or perhaps denied to do so. This reflects a common clinical problem in the ED and indicates that a specific poisoning diagnosis cannot be difficult to establish. Furthermore, lack of precision in coding procedure may contribute to unspecific diagnoses.

In conclusion, we found QTc prolongation in a mixed population of patients with suspected poisoning in the ED of two Swedish and two Danish hospitals to be associated with a threefold risk of 30-day all-cause mortality or cardiac arrest and an absolute risk of 3.2%.

Contributors CSH designed the study, interpreted the results and drafted the paper. AP analysed the data. All authors conceived the study. ATL, AP and HKJ critically reviewed the paper, assisted with interpretation of the results and have approved the final edition. CSH takes responsibility for the final paper.
