The Association of MRI Findings and Long-Term Disability in Patients With Chronic Low Back Pain

Peter Muhareb Udby, MD, DC, PhD1,2,3, Ø, Søren Ohrt-Nissen, MD, PhD2,4, Tom Bendix, DmSci2, Stig Brorson, MD, PhD, DmSci1,6, Leah Y. Carreon, MD, MSc3,7, and Mikkel Østerheden Andersen, MD3

Abstract

Study Design: Longitudinal cohort study with 13-year follow-up.

Objective: To assess whether long-term disability is associated with baseline degenerative magnetic resonance imaging (MRI) findings in patients with low back pain (LBP).

Methods: In 2004-2005, patients aged 18 to 60 years with chronic LBP were enrolled in a randomized controlled trial and lumbar MRI was performed. Patients completed the Roland-Morris Disability Questionnaire (RMDQ) and the LBP Rating Scale, at baseline and 13 years after the MRI. Multivariate regression analysis was performed with 13-year RMDQ as the dependent variable and baseline disc degeneration (DD, Pfirrmann grade), Modic changes (MC), facet joint degeneration (FJD, Fujiwara grade) smoking status, body mass index, and self-reported weekly physical activity at leisure as independent variables.

Results: Of 204 patients with baseline MRI, 170 (83%) were available for follow-up. Of these, 88 had Pfirrmann grade >III (52%), 67 had MC (39%) and 139 had Fujiwara grade >2 (82%) on at least 1 lumbar level. Only MC (β = 0.15, P = .031) and weekly physical activity at leisure (β = −0.51, P < .001) were significantly, negatively associated with 13-year RMDQ-score (R² = 0.31).

Conclusion: DD and FJD were not associated with long-term disability. Baseline MC and weekly physical activity at leisure were statistically significantly associated with less long-term disability.

Keywords
Modic changes, disability, low back pain (LBP), degeneration, MRI, long-term follow-up

Introduction

Since the first reports on human magnetic resonance imaging (MRI) in 1977, there has been a vast advancement in its use and functions.1 For patients suffering from back pain and its associated disability, it has become a commonly used diagnostic imaging modality. Whereas certain imaging findings such as nerve impingement and severe canal narrowing has shown a strong association with patient-reported outcomes (PROs), other signs of degeneration found on MRI have a more questionable clinical relevance.2-7 Disc degeneration (DD), Modic changes (MC), and facet joint degeneration (FJD) are all imaging findings and possible causes of LBP.5,8-10 Several different grading systems have been utilized to classify the severity of these degenerative changes. The Pfirrmann classification system has been validated, with excellent inter- and intraobserver agreement, and is widely used to classify DD in 5 grades, Pfirrmann grade I (normal) to V (most severe).11,12 MC, also termed vertebral endplate signal changes (VESC), are endplate and adjacent vertebral body marrow changes visible on MRI. They have been histologically described, and MRI classified into 3 different types, MC 1 to 3.13,14 Their presence,
size, location, and the MRI inter- and intraobserver reliability, substantial to an almost perfect agreement, has been validated across studies.\textsuperscript{5,16} Facet joint changes and degeneration is a common feature, which can be graded on both oblique radiographs, computed tomography (CT) scan, and MRI.\textsuperscript{5,17} The radiographic assessment of lumbar facet joints is possible through 12 different grading systems.\textsuperscript{18} The reliability of these systems has been evaluated with varying inter- and intraobserver agreement.\textsuperscript{18,19} The standard MRI grading system used for lumbar FJD, with an almost perfect interobserver agreement, was developed by Fujiwara et al.\textsuperscript{9,18} The system developed by Fujiwara classifies facet joint changes into grade 1 (normal) to grade 4 (severe degeneration).\textsuperscript{9}

Several studies have focused on these degenerative imaging findings in the spine and their clinical relevance.\textsuperscript{3,20,21} Few studies, however, have examined the long-term association between such findings and spine-related disability.\textsuperscript{22} The aim of the study was to assess whether baseline MRI findings indicating degeneration are associated with long-term disability in patients with LBP.

**Materials and Methods**

This is an observational cohort study with 13-year follow-up of patients with chronic LBP. The cohort was originally recruited for a randomized control trial (RCT) conducted between 2004 and 2005. The cohort and original study details have been described in previous studies.\textsuperscript{7,23}

Of the original 207 patients in the RCT, 204 had a lumbar MRI performed at baseline. Based on these MRIs, patients were, for the current study, described regarding 3 different radiological parameters:

- DD defined as Pfirrmann grade >III on any lumbar level.\textsuperscript{5,24}
- MC as described by Modic et al, any type on any lumbar level.\textsuperscript{13,14,25}
- FJD defined by Fujiwara grade >2 on any lumbar level.\textsuperscript{9}

Study participants completed questionnaires with PRO’s at baseline and at 13-year follow-up, including the Roland-Morris Disability Questionnaire (RMDQ), and the LBP Rating Scale for activity limitations survey (RS).\textsuperscript{26-28} Demographic data including smoking, body mass index (BMI), and weekly physical activity at leisure (PA) was also recorded both at baseline and at 13-year follow-up. Information regarding antibiotic use, defined as any received course of antibiotics, and spine surgery during the 13-year period was obtained through the follow-up questionnaire.

**MRI Evaluation**

All patients underwent a low-tesla MRI of the lumbar region (0.2-T MRI system, Siemens Open Viva). The use of low-field MRI was widely used in the inclusion period from 2004 to 2005. Excellent reliability between low- and high-field MRI has been demonstrated for lumbar degenerative changes.\textsuperscript{29} MRIs were evaluated by an experienced musculoskeletal radiologist using a standardized evaluation protocol and unaware of the clinical status of the individual patient.\textsuperscript{23} The MRI description was not available to included patients and did not influence treatment.

**Ethical Considerations, Approvals, and Registration**

Protocol, data collection, and study ethics were approved by the National Data Protection Agency and The Regional Committees on Health Research Ethics (reference number: S-20172000-77).

**Statistical Analyses**

All analyses were performed using IBM SPSS version 24. Patients with a baseline MRI, baseline and 13-year follow-up questionnaires were included in the analysis. Multivariate linear regression analysis was performed with 13-year RMDQ and RS as dependent variables and DD, MC, FJD as independent variables. Demographic data at 13-year, including smoking, BMI, and PA was included as covariates in the regression models. The association between 13-year RMDQ and the independent variables was evaluated by the standard β coefficient. The goodness-of-fit and explained variation were evaluated by $R^2$.

**Results**

A total of 290 patients fulfilled the criteria for inclusion in the original study, 207 were enrolled with 204 having lumbar MRI and being eligible for inclusion in the current study (Figure 1). Of these, 170 patients (83%) completed their questionnaire at 13 years, 88 had DD (52%), 67 had MC (39%), and 139 had FJD (82%) on their baseline MRIs. Of the 34 dropouts, no difference was seen regarding baseline data on the distribution of spine degeneration on MRI. Demographics for 13-year follow-up data are described in Table 1.

In patients with MC, MC-1 was present in 75% of patients, and mixed (MC-1 and MC-2) in <1% of patients, and mixed (MC-1 and MC-2) in 6% of patients. Baseline and follow-up PROs for the entire cohort are presented in Table 2.

Both MC and PA at leisure were found to be statistically significantly negatively associated with 13-year RMDQ-scores, $R^2 = 0.31$ with standard β coefficients of 0.15 for MC ($P = .031$) and −0.51 for PA ($P < .001$). Neither DD (β = 0.060, $P = .406$) nor FJD (β = −0.017, $P = .801$) showed any statistically significant association with long-term disability. Smoking status (β = 0.102, $P = .127$) and BMI (β = 0.092, $P = .179$) also showed no significant association with the RMDQ scores.

Similar results were found for 13-year RS with $R^2 = 0.26$ and β of −0.18 for MC ($P = .015$) and −0.45 for PA ($P < .001$). DD, FJD, smoking status, and BMI did not significantly affect long-term RS.
Disability measured by RMDQ and RS improved over time, resulting in less disability at 13-year follow-up compared with baseline. LBP also decreased from 6.2 (Numeric Rating Scale [NRS]) to 4.5 (NRS) over the 13-year time period. Leg pain increased slightly, from 2.1 (NRS) to 3.0 (NRS) at final follow-up. The consumption of back pain medication decreased from 65% of the group using regularly at baseline to 56% of the group using regularly at 13-year follow-up. There was no change in PA over the 13-year span.

**Discussion**

Lumbar MRI scans are used to identify the possible causes of back pain, to guide treatment, and as a tool to provide short- and long-term prognosis. In this study, the association between long-term disability and baseline MRI findings was examined in chronic LBP patients. Degenerative changes were found to be present in the majority of patients—DD and FJD in, respectively, 52% and 82% of all patients. Similar results have been found in previous studies of MRI degeneration in patients with LBP.3,10,30

Neither DD at baseline, defined as Pfirrmann grade >III on any lumbar level, nor FJD, defined as Fujiwara grade >2 on any lumbar level, was associated with disability at long-term follow-up. Similar results on the prevalence and limited or lacking association with back pain and disability have been documented in cross-sectional studies and studies with shorter follow-up periods.3-5,8,31,32

Subgroup analysis of the cohorts stratified by imaging findings was not performed in this study, as there was a substantial overlap of patients with 2 or all 3 of the possible imaging findings denoting degeneration. It would be difficult to isolate patients with DD without FJD as well as patients with MC without DD. This overlap of imaging findings has been described, in particular in relation to MC and DD, previously.7,14,25,33

Degenerative disc disease is a commonly used diagnosis and possible indication for spinal fusion in patients with chronic back pain.31,34 However, the term degenerative disc disease is...

Baseline: MRI findings at the start of the study. 13-year follow-up: MRI findings at the end of the study.

used broadly across studies and should be avoided unless thoroughly defined. In this study, the Pfirrmann and Fujiwara classification systems were used to grade the degenerative MRI findings of the intervertebral discs and the facet joints, respectively.

For DD, the Pfirrmann classification is the most validated and second most used for LBP patients across studies.11,12,24,26 MC was originally described based not only on MRI changes but also histological changes examined in a few cases by Modic et al.13,14,25 Although it is possible to add information, including size, location, distribution, and so on, to the MC description; it is still the original MC classification of MC type 1 to 3 that is being utilized and validated across studies.8,13,15,16,35,36

It has been questioned whether the classification of MC is related to the MRI field strength—with low-field MRI scanners (defined by fields ≤0.3 T) showing an increased number of MC type-1 compared with high-field MRI (defined by fields ≥1.0 T) scanners showing an increased number of MC type-2.25

In general, excellent reliability between low- and high-field MRI has been demonstrated for lumbar degenerative findings, including disc herniation and lateral stenosis.20 For FJD, the classification systems suffer from certain limitations. Degeneration including osteoarthritis has been described on different imaging systems, including X-rays, CT, and MRI scans.18,19 Some of the grading systems have been adapted from CT to MRI but with limited validation in inter- and intraobserver studies.9,17,19,38 The Fujiwara classification has been examined and found to be reproducible in grading FJD in MRI analysis.9,18

Limitations of this study include possible confounding in terms of different exposure, treatment, and psychosocial factors of the individual patients within the cohort. There could be a possible bias with a single-rater radiologist; however, previous studies have shown excellent interrater reliability and therefore a reliability assessment was not included in the present study.11,12,15,16,18

The primary strengths of this study include a high follow-up rate of 83% at 13 years and the inclusion of relevant potential confounders in the statistical analysis, BMI, smoking, and so on. Also, no patients underwent long-term antibiotic courses aimed at eradicating possible bacterial agents within the disc, including Propionibacterium acnes.39,40

The findings in this study are in accordance with previous studies, showing that lumbar degenerative changes visualized by MRI are common and are to be expected to a certain degree in all mature individuals.3,5,8,17,41-45 However, this cohort study of patients with chronic LBP found more severe degeneration on MRI compared with what is found in cross-sectional population-based MRI studies.3-5,10,30,33 The clinical relevance of these results is the prognostic value at long-term follow-up of patients with LBP. Some studies with short-term follow-up and cross-sectional studies have found an association between MC in particular type-1, severe disc degeneration, and to some degree facet joint degeneration, with LBP.31,32,46,47 In this study, no association was found between baseline MRI findings and 13-year disability in LBP patients with severe DD or FJD. This highlights the limited prognostic value of a single baseline MRI scan on long-term disability.

MC present at baseline was predominantly MC type-1, 75%, this finding was associated with statistically significant less long-term disability in the cohort.7 These results are in contrast to short-term studies.8,33,39,47 Several studies have investigated the effect of both surgical and antibiotic treatment of patients with MC and LBP.39,48,49 The relevance of such invasive treatments or prolonged antibiotic courses of patients with MC can be questioned. In particular, if the MRI findings are not associated with a worse prognosis at long-term follow-up in patients not receiving treatment.22

It is striking that in a between-individual view, DD and MC are rather highly associated with LBP, whereas a longitudinal view within individuals does not show such an association.7,22,45,50 One hypothesis could be that the degenerative process of the disc, including the gradually fibrotic nuclear pulposus and annulus, reduces the risk of disc penetration and thereby activation of peripheral nerve fibers within the disc.

In future studies, it would be interesting to verify the histologic and MRI transgression of MC over time including the timeline and clinical relevance; to further examine the prognostic properties of baseline degeneration found on MRI combined with clinical findings, on long-term PROs in patients with LBP; and to evaluate the long-term outcomes in
patients with degeneration on MRI and LBP not undergoing treatment.

**Conclusion**

Degeneration on MRI was a frequent finding in patients with LBP. None of the MRI changes suggesting degeneration were associated with a worse outcome at 13-year follow-up. Baseline MC was associated with statistically significant less long-term disability.

We encourage further studies to validate these findings and assess the long-term clinical consequences of abstaining from treatment in patients with LBP.
